GEOLOGY AND GROUND-WATER RESOURCES OF LAMB COUNTY, TEXAS

By

E. R. Leggat, Geologist

United States Geological Survey

March 1957

ABSTRACT

This report describes the geology and ground-water resources of Lamb County in the southern High Plains of Texas. The county has an area of 1,022 square miles. The surface drainage is into numerous ephemeral ponds and three intermittent tributaries of the Brazos River - Running Water Draw, Double Mountain Fork of the Brazos River, and Yellow House Draw. About 150 square miles in the western part of the county is covered by sand dunes.

The Ogallala formation, of Tertiary age, is the most important aquifer in the county, and it supplies all water for municipal use and for irrigation. The number of irrigation wells in Lamb County increased from about 75 in 1937 to 1,719 in 1951, and as a result the withdrawal of ground water increased from about 17,000 acre-feet in 1937 to an estimated 210,000 acre-feet in 1951. The saturated thickness of the Ogallala formation is greatest in the northwestern part of the county, where it exceeds 200 feet, and diminishes toward the south to less than 50 feet. The depth to water ranges from about 5 feet below the land surface in the area adjoining the sand-hills to more than 180 feet in the southwestern part of the county.

The ground water in the sand and gravel of the Ogallala formation is unconfined. The water enters the underground reservoir from precipitation on the county and on areas to the northwest. Most of the precipitation that falls in light or moderate amounts in Lamb County is lost by evapotranspiration and does not reach the water table. However, during heavy rains considerable recharge takes place from runoff into the depressions and stream beds and by direct infiltration through the soil in areas of sand dunes or very sandy soil and subsoil. The amount of recharge cannot be estimated from the available data. The discharge of ground water, in addition to that from wells, includes approximately 4,500 to 5,000 acre-feet of ground water discharged annually by evapotranspiration in areas where the water table is near the surface, and an unknown amount of underflow to counties downgradient to the east and southeast.

Water levels in observation wells have declined persistently since 1943 except in wells that are remote from pumping or that are marginal to the irrigated regions. In these areas the water levels have declined little, and in some wells they were at a higher stage in 1953 than in 1938. Subnormal precipitation together with the increased rate of withdrawal for irrigation during 1952 caused the water levels in observation wells to decline more than in any previous year, however. Although pumping has decreased the quantity of water in storage, it is estimated that 12 million acre-feet of ground water is still available in the county. A large potential supply of ground water for municipal and industrial use is available from the 150 square miles of sandhills, where about $\frac{3}{4}$ million acre-feet of the total of 12 million in the county is stored.

The ground water is generally of satisfactory quality for most purposes, although it is very hard and rather high in bicarbonate content. In the areas near alkali lakes and in the vicinity of seeps, it is highly mineralized.

Although the Permian sedimentary rocks are important producers of petroleum, they are unimportant as a potential source of ground water. The sandstones of Triassic age have not been tested thoroughly for water, but electric logs and test-well data in adjacent regions indicate that they will not yield large supplies of fresh water. In the southern part of the county, several domestic wells are reported to draw mineralized water from the basal sand and gravel of the Cretaceous.

INTRODUCTION

PURPOSE AND SCOPE

The purpose of this report is to discuss the geology of Lamb County, Tex., as it is related to the occurrence and development of ground water; to bring up to the date of the field work (1952) the records of wells and the fluctuations of water levels; to describe the water-yielding properties of the water-bearing formations; and to describe the chemical character of the ground water. The investigation in Lamb County was made possible through cooperation between the Texas State Board of Water Engineers and the U. S. Geological Survey and is a part of a Statewide program of study of the ground-water resources.

The investigation was started in the spring of 1950 by J. C. Albert and J. W. Garrett and was continued in 1951 and 1952 by J. Q. Frizzell and G. E. Welder. The writer completed the field studies in 1952. The report includes records of 1,742 wells, of which 1,719 are used, or were formerly used, for irrigation (table 8); drillers' logs of 172 wells (table 9); records of water-level measurements in 45 wells (table 10); chemical analyses of water from 88 wells, 2 springs, and a lake (table 11); a map showing the locations of the wells and other features described (pl. 1); and cross sections showing the generalized geology (pls. 2 and 3).

The field work was supervised by W. L. Broadhurst, former District Geologist, and the report was prepared under the supervision of R. W. Sundstrom, District Engineer of the Geological Survey in charge of ground-water investigations in Texas. The entire program was carried out under the general direction of A. N. Sayre, Chief of the Ground Water Branch of the U. S. Geological Survey.

PREVIOUS INVESTIGATIONS

No detailed investigation of the geology and ground-water resources of Lamb County has been made prior to this study. However, numerous reports have contained general information on the geology and ground-water conditions of the county. Johnson (1901-02) reported on the utilization of the High Plains and discussed the physiography, underground waters, and land economy. Baker (1915) made reference to geologic and hydrologic conditions in parts of Lamb County. Theis, Burleigh, and Waite (1935) described briefly the water-bearing formations and the depth to water in the southern High Plains. An inventory of water wells in Lamb County was made in 1937 by Broadhurst and McCarty (1938). Since 1938 the annual reports of the U. S. Geological Survey on water levels and artesian pressures in the United States have included a chapter on the observation wells in Lamb County. The public water supplies of Amherst, Littlefield, Olton, and Sudan were described by Broadhurst, Sundstrom, and Weaver (1949). Seven progress reports have been written since 1936, which discuss the geology and ground water in the irrigated region of the southern High Plains in Texas. A summary of the fluctuations of water levels in the southern High Plains, which includes Lamb County, was published in 1951 (Leggat). Brand (1953) made a detailed study of the Cretaceous rocks of the Llano Estacado, including part of Lamb County.

LOCATION

Lamb County is in the southern High Plains of Texas and is bounded on the north by Castro and Parmer Counties, on the east by Hale County, on the south by Hockley County, and on the west by Bailey County (fig. 1). Most of the county lies between $34^{\circ}20'$ and $33^{\circ}50'$ north latitude and $102^{\circ}05'$ and $102^{\circ}35'$ west longitude. It has an area of 1,022 square miles and, according to the U. S. Bureau of the Census, had a population of 20,015 in 1950. Littlefield, which had a population of 6,558, is the county seat and principal shipping and trading center. Littlefield is 37 miles northwest of Lubbock, 24 miles southeast of Muleshoe, and 45 miles southwest of Plainview.

Bulletin 5704

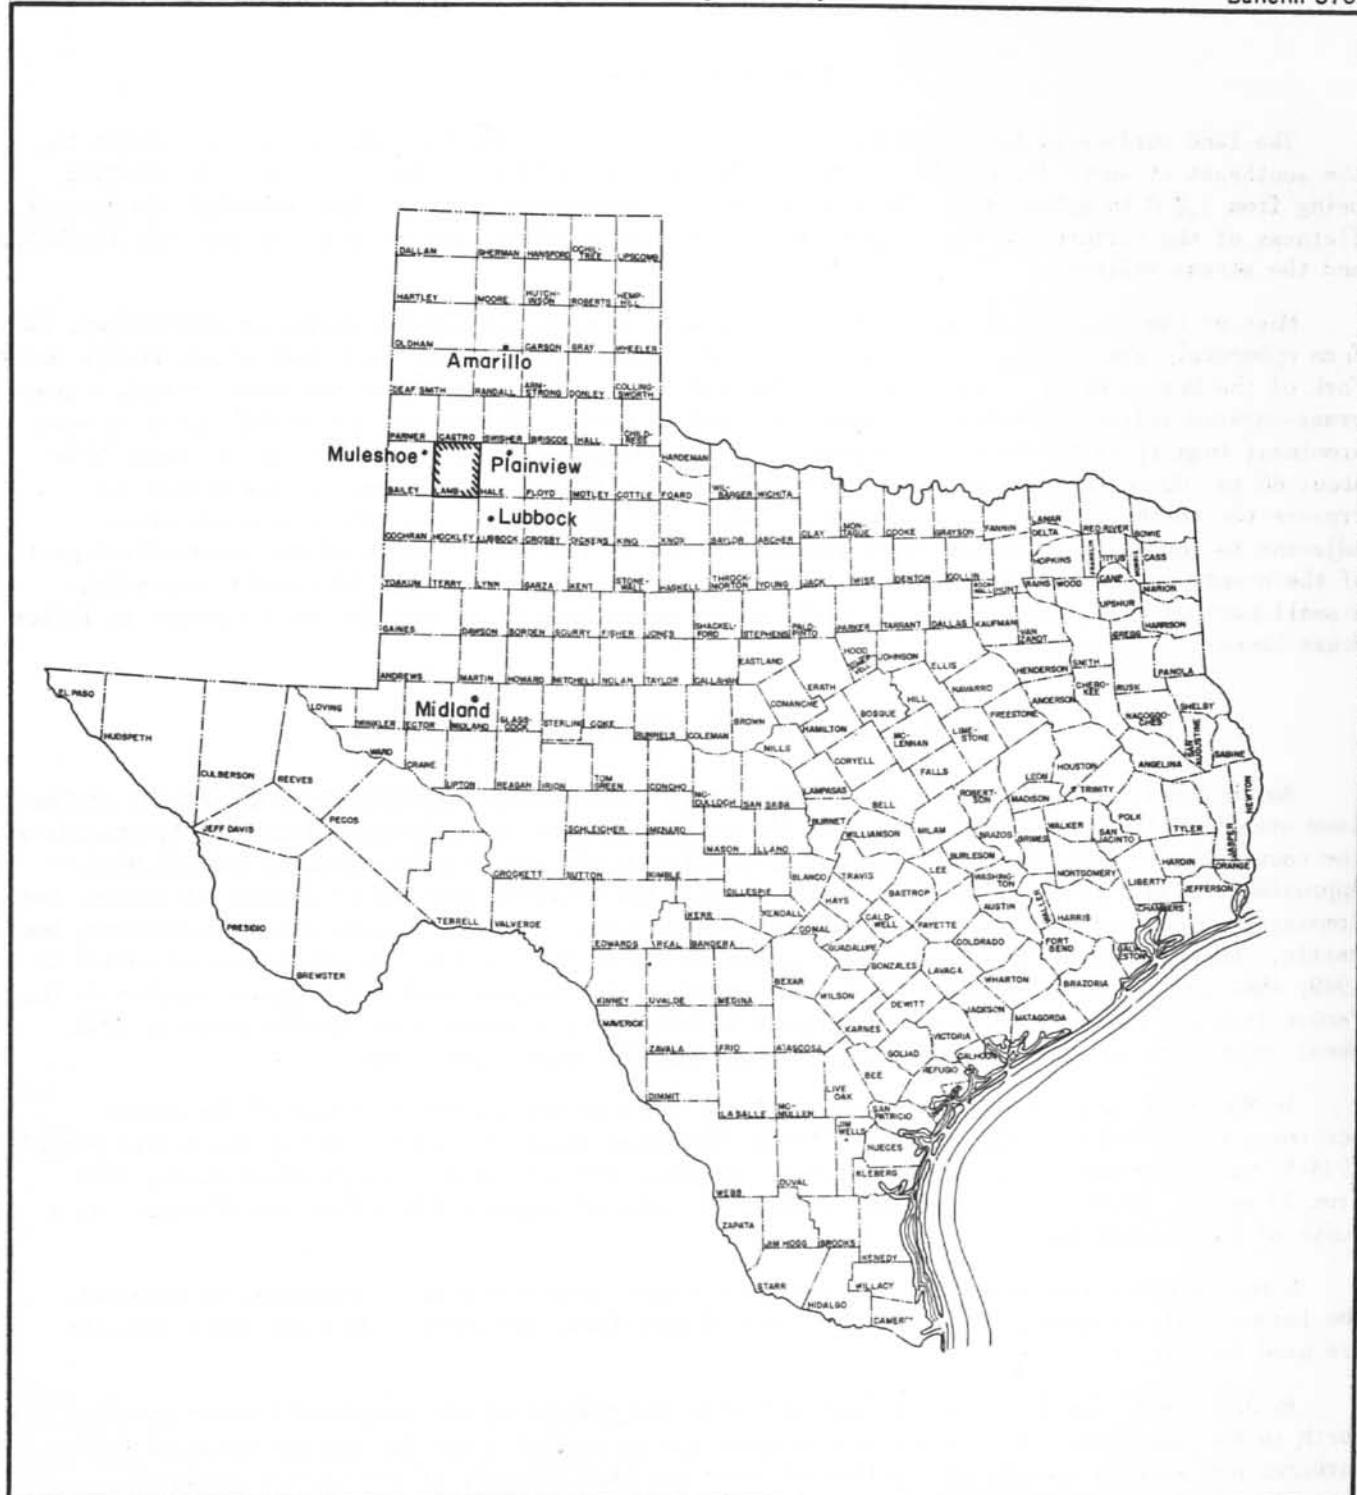

FIGURE 1.- Map of Texas showing location of Lamb County

Transportation facilities include several paved Federal and State highways and numerous paved farm-to-market roads. The Panhandle and Santa Fe Railway serves Littlefield, Amherst, and Sudan.

TOPOGRAPHY AND DRAINAGE

The land surface of Lamb County is nearly level to gently rolling and, in general, slopes to the southeast at about 10 feet to the mile. The total relief is 460 feet, the range in altitude being from 3,370 to 3,830 feet. The most prominent topographic features that interrupt the general flatness of the surface are the numerous dish-shaped depressions, several playa basins, the sandhills, and the stream valleys.

Most of the drainage of the county is into these dish-shaped shallow basins or depressions, which form ephemeral lakes during occasional periods of heavy rainfall. The North Fork of the Double Mountain Fork of the Brazos River rises in eastern New Mexico and meanders east and southeast through a broad grass-covered valley, crossing the sandhills south of Earth. Beyond this point the valley is more prominent than it is to the west, ranging in width from about 500 to 3,500 feet and in depth from about 60 to 100 feet. Running Water Creek which seldom flows, rises in eastern New Mexico and crosses the northeast corner of the county. These intermittent streams, draining small areas adjacent to the valleys, rarely carry floodwaters out of the county. Much of the southwestern part of the county is drained into large alkali lakes, or playas, such as Bull Lake and Illusion Lake. A small part of the southeast corner of the county is drained by an intermittent tributary to Yellow House Creek.

AGRICULTURAL AND INDUSTRIAL DEVELOPMENT

Agriculture is the principal source of income in the county. Approximately 80 percent of the land area is cultivated and 40 percent of the cultivated area is irrigated. According to records of the county agent, farm income in 1949 was about \$24,900,000 and in 1950 was about \$40,000,000. Approximately 90 percent of the farm income in 1950 was obtained from the production of cotton; the remaining 10 percent came from grain sorghum, wheat, alfalfa, peanuts, sudan grass, vegetables, beef cattle, and dairy products. Lamb County ranked fourth in the State in the production of cotton in 1949, when 192,277 bales were produced. The county is the largest producer of grain sorghum in the Panhandle-South Plains area, about 10,400,000 bushels being produced from 260,000 acres in 1950. Wheat production in 1949 and 1950 averaged about 225,000 bushels per year.

In May 1944, oil was discovered in the Anton field in the southeast corner of the county. According to the Railroad Commission of Texas, the total production of oil during the 8-year period 1944-51 was approximately 1,553,000 barrels. Of this, 317,669 barrels was produced during 1950 from 30 wells. Most of the petroleum is found in rocks of supposed Clear Fork age (Permian) at a depth of about 6,000 feet.

Deposits of caliche near the land surface are used extensively for road-surfacing material. The largest caliche quarry is at the south end of Bull Lake, but other widely scattered deposits are used locally.

In June 1952, the first unit of a 3-unit electric powerplant was completed 5 miles south of Earth in the sandhills. This plant uses natural gas to produce steam for the operation of the turbines and uses an average of 1 gallon of water for each kilowatt of electricity produced. When completed, the plant will have a capacity of 250,000 kilowatts.

CLIMATE

The climate of Lamb County is semiarid and is characterized by a wide range in temperature, low precipitation, and high evaporation. Records at Littlefield are incomplete; therefore, most of the following climatological data were obtained from records of the U. S. Weather Bureau at Muleshoe in Bailey County. The highest and lowest temperatures recorded over a period of 23 years were 110°F and -21°F. The average annual temperature is about 57°F; average monthly temperatures are shown in figure 2. The approximate dates of the last killing frost in spring and the first killing frost in autumn in Littlefield are April 19 and November 4. Thus, the average length of the growing season is about 200 days.

Annual precipitation at Muleshoe during the period 1922-52, inclusive, averaged 18.25 inches. Of this nearly three-quarters was recorded during the 6-month growing season from April to September, inclusive (table 1). The annual precipitation and the cumulative departure from normal precipitation are shown in figure 3, and the maximum, minimum, and average monthly precipitation are shown in figure 4. Records of daily precipitation indicate that, on the average, some moisture will fall during 45 days of the year. Of this precipitation, 53 percent is in amounts of less than 0.5 inch per day, and about 90 percent in amounts of less than 2 inches per day (fig. 5). The frequency-of-precipitation curve (fig. 6) indicates that a 3-inch rain in 24 hours may be expected only once in about 6 years, whereas a 2-inch rain may be expected almost every 2 years.

Figure 2 lists the average monthly evaporation from a free-water surface as determined from records of the Texas Agricultural Experiment Station at Lubbock. These records, which are probably representative of conditions in Lamb County, indicate that the average annual evaporation from a free-water surface is about 60 inches, or about three times the average annual precipitation. Even during the growing season, when precipitation is greatest, but when soil-moisture demand also is greatest, evaporation is about three times the available precipitation.

ACKNOWLEDGMENTS

Appreciation is expressed to the many farmers, well drillers, pump dealers, oil companies, and the public-service company who generously contributed information and cooperated in obtaining field data. Acknowledgment is made also for the information furnished by officials of the several cities and the Federal and State agencies, including the Soil Conservation Service of the U. S. Department of Agriculture and the Extension Service of the Agricultural and Mechanical College of Texas. R. W. Imlay of the U. S. Geological Survey identified several fossils which were collected during the investigation.

GEOLOGIC FORMATIONS AND THEIR WATER-BEARING PROPERTIES

GENERAL GEOLOGY

Almost all of Lamb County is underlain by unconsolidated sediments of Pliocene or younger age, and the oldest rocks penetrated by wells are of Permian age. The principal aquifers in the county are sands and sandstones of Pliocene age.

Sedimentary rocks of Permian age were deposited in an elongated trough, the axis of which trends north-south and passes a short distance east of Lamb County. The depositional environment changed gradually from marine in earliest Permian time to continental at the close of the period. After the close of Permian time, continental sedimentary rocks of Triassic age were deposited by streams that flowed probably from the west and northwest (Adams, 1929). Subsequent erosion removed a part of the Triassic deposits and any overlying Jurassic deposits that may have been present. Marine sediments of Cretaceous age were deposited upon the eroded Triassic surface by an advancing sea during Comanche time. Post-Cretaceous erosion removed practically all the sediments of Cretaceous age north of line A-A' (fig. 7), and left a maximum thickness of 115 feet of Cretaceous deposits south and southwest of the line. The Pliocene sediments that rest unconformably on the eroded surface of Triassic and Cretaceous rocks are of continental origin and were deposited by streams that had their headwaters in the Rocky Mountains. Sedimentary rocks of Pleistocene age occur in many of the depressions and stream valleys. Recent eolian deposits of sand and silt mantle most of Lamb County.

Geologic cross sections are shown on plates 2 and 3. The thickness, physical character, and water-bearing properties of the geologic formations penetrated in wells in Lamb County are given in table 2.

PERMIAN SYSTEM

The rocks of the Permian system do not crop out in Lamb County but have been encountered in oil tests. The upper Permian rocks closely resemble the overlying red shales of the Triassic system, although the characteristic maroon color and mica content of the Triassic shales are rare in the Permian formations. The thickness of the Permian rocks was reported to be about 7,000 feet in an oil test drilled near Littlefield in 1954, by the Texas Co.

The Permian rocks consist of red shale, clay, sandstone, gypsum, dolomite, and limestone. Although no water wells in Lamb County have penetrated Permian rocks, electric logs of oil tests indicate that the water is highly mineralized.

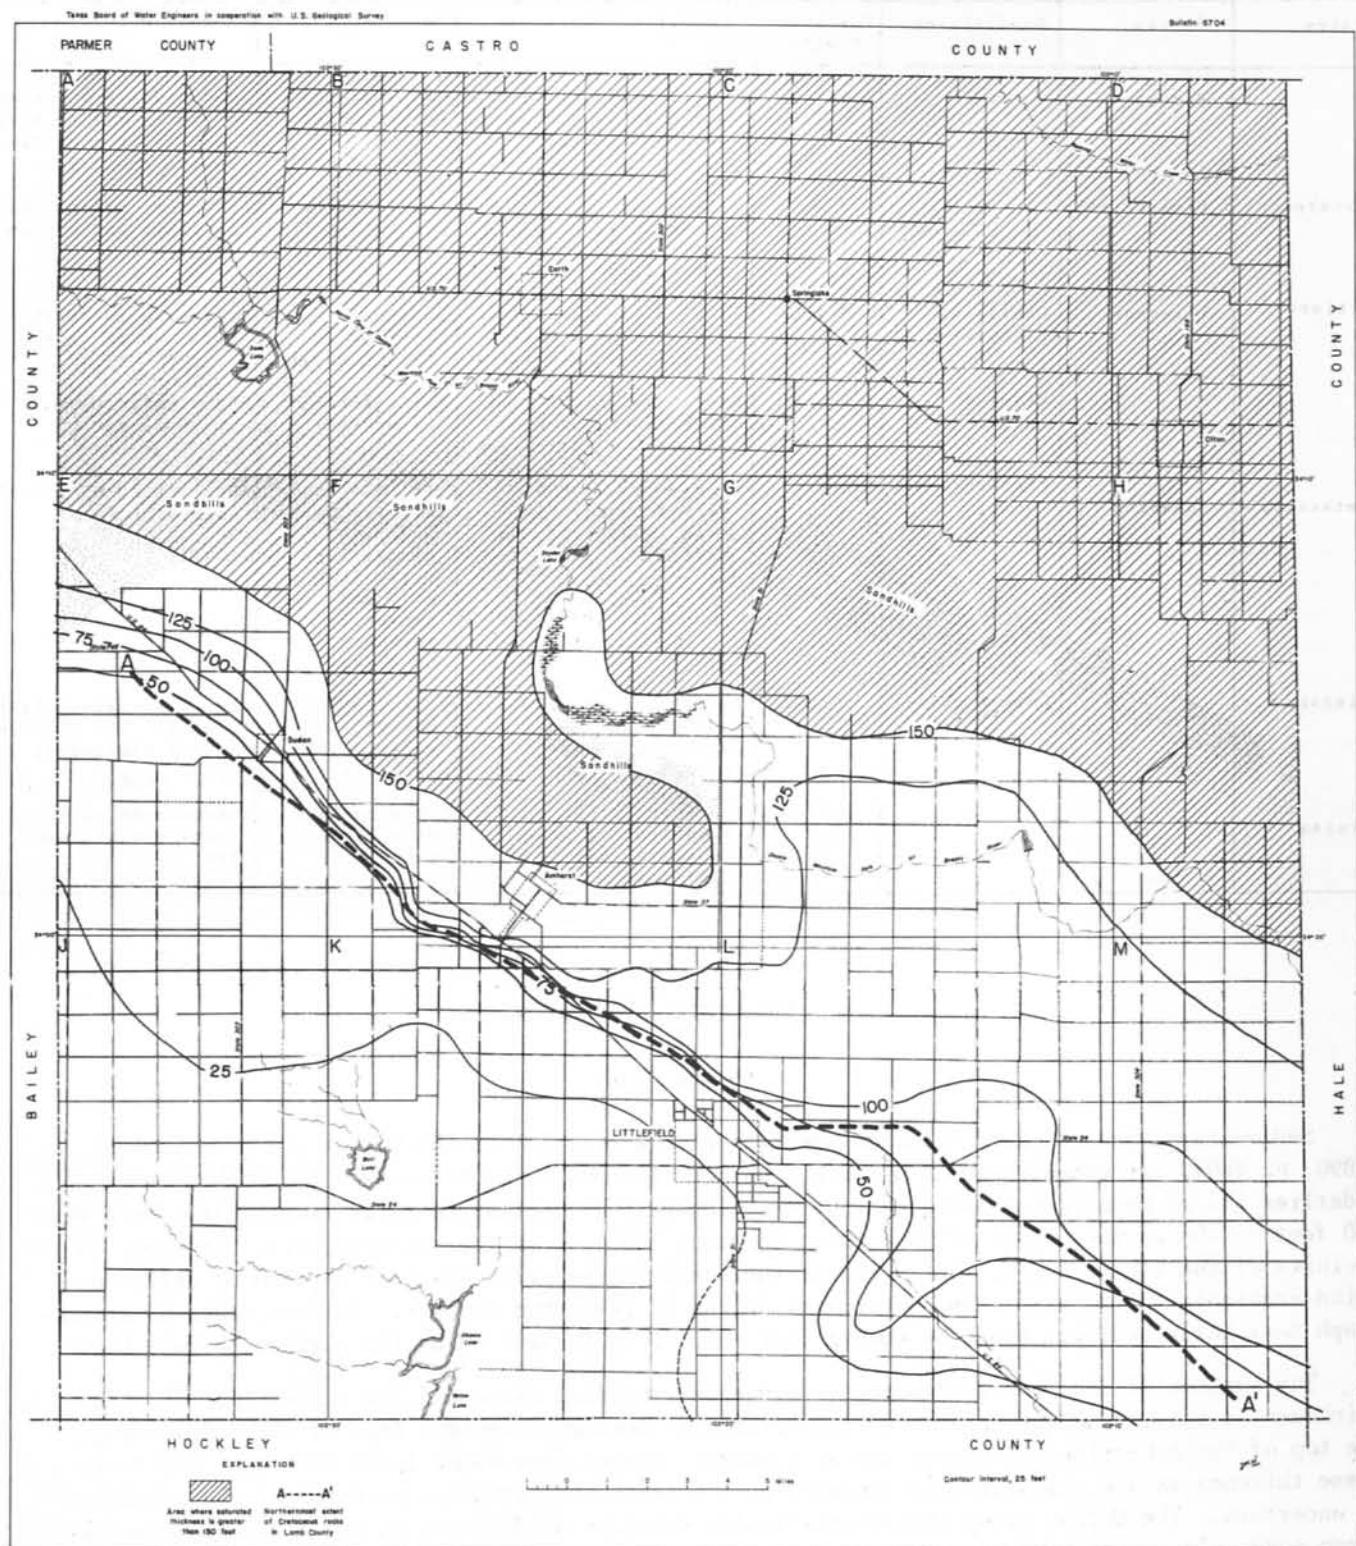

FIGURE 7.-Saturated thickness of Ogallala formation in Lamb County, Tex.

Table 2.- Geologic formations in Lamb County

System	Series	Subdivision	Thickness (feet)	Physical character	Water supply	Remarks
Quaternary	Recent	--	0- 40	Eolian sand, playa silt and clay, and channel sand and gravel	Not a source of water supply	Sand dunes and channel deposits aid recharge; playa-silt and clay retard recharge
	Pleistocene	--	?	Silt, clay, sand, gravel, fresh-water limestone, and caliche	Not a source of water supply	Lie above water table in playa and stream valleys
Tertiary	Pliocene	Ogallala formation	0-250+	Clay, silt, fine- to coarse-grained sand, gravel, and caliche	Principal aquifer in Lamb County	Decreases in thickness toward south
		Washita group	0- 15	Limestone, light-gray to yellow, and brown and yellow shale	Not a source of water	Represented by Duck Creek formation
Cretaceous	Comanche	Fredericksburg group	0-100	Limestone, blue and yellow shale, clay, sand, sandstone and gravel	Yields small quantities of moderately mineralized water from sand and gravel in southern part of county	Represented by Kiamichi formation
Triassic		Dockum group	1,500±	Variegated shale, sandy clay, and micaceous sandstone	Contains highly mineralized water so far as known	Underlies all of Lamb County. Has not been tested thoroughly for water supply.
Permian			7,000±	Red shale, clay, sandstone, gypsum, dolomite, and limestone	Contains highly mineralized water	Encountered only in tests for oil and gas

TRIASSIC SYSTEM

DOCKUM GROUP

Sedimentary rocks of Late Triassic age, which were assigned to the Dockum group by Cummins (1890, p. 189), are encountered in wells but do not crop out in Lamb County. The Dockum group underlies all of Lamb County and is encountered in wells at depths generally ranging from more than 250 feet in the northern part of the county to about 140 feet in the southern part. However, in the vicinity of the alkali lakes, where most of the overlying material has been removed by deflation (wind erosion), the Dockum is encountered at depths of less than 50 feet. In fact, logs of seismograph test holes indicate that the Dockum lies about 5 to 10 feet below the surface in Bull Lake.

The surface of the Dockum group has a moderately uniform slope and low relief (pl. 3). The thickness of the Dockum, as determined from drillers' logs and electric logs of oil tests using the top of the anhydrite of Permian age as a marker, ranges from about 1,340 feet to 1,660 feet. These thicknesses are somewhat questionable, as the exact stratigraphic position of the anhydrite is uncertain. The Dockum group characteristically consists of dark-red to maroon shale, grayish-green sandy clay, and gray to red micaceous sandstone.

Although the sandstones of the Dockum group have not been completely penetrated by water wells in Lamb County, electric logs of tests for oil and gas indicate the presence of water too highly mineralized for irrigation or public use. Similar information regarding the quality of water in the Dockum was obtained from several exploratory wells drilled in Floyd, Lubbock, Bailey, and Cochran Counties. The chemical analysis of a sample of water from a well drilled into the Dockum group by the city of Lubbock in 1949 showed 35,000 ppm (parts per million) of dissolved solids and 12,000 parts of chloride. The water was obtained from the Santa Rosa sandstone of the Dockum group at a depth of 900-940 feet. A well testing the sandstone in southwestern Floyd County yielded water that contained 13,700 ppm of dissolved solids and 7,320 parts of chloride. The yield of this well decreased from 250 to 150 gallons a minute (gpm) after 72 hours of pumping. An exploratory well testing the Dockum group 1 mile west of the Lamb-Bailey County line was reported to have yielded an insufficient supply of water for irrigation after a 10-minute period of pumping. The chemical analysis of a drill-stem sample of water from the Dockum group in Cochran County showed 2,070 ppm of dissolved solids and 590 parts of chloride. However, in a preliminary pumping test the well yielded only 15 gpm and had a specific capacity of 0.3 gpm per foot of drawdown.

Available data suggest that the water in the Dockum group in Lamb County is too highly mineralized for most purposes, but that the mineralization decreases toward the area of outcrop in New Mexico. The yield of the Triassic sandstones in general, is insufficient for irrigation, municipal, or industrial supplies.

CRETACEOUS SYSTEM

COMANCHE SERIES

Rocks of the Comanche series of Early Cretaceous age rest on the eroded surface of Triassic rocks and crop out along the western margins of Bull Lake and Illusion Lake. Logs of wells show that Cretaceous rocks are present only south and southwest of line A-A' (fig. 7). Figure 7 and plate 3 show the subsurface position of the prominent northeast-facing scarp that resulted from the removal by post-Cretaceous erosion of Cretaceous rocks north and northeast of line A-A'.

The Comanche rocks in Lamb County consist of shale, limestone, sandstone, sand, and gravel, and include rocks of the Fredericksburg and Washita groups. Logs of seismograph test holes and geologic exposures in Bull Lake indicate an aggregate thickness of about 115 feet.

FREDERICKSBURG GROUP

The Fredericksburg group in Texas is divided into four formations, which are, in ascending order, the Walnut clay, the Comanche Peak limestone, the Edwards limestone, and the Kiamichi formation. It is believed that only the Kiamichi formation is present in Lamb County.

Kiamichi formation. - The Kiamichi formation crops out along the western margins of Bull Lake and Illusion Lake and is encountered in wells south and southwest of line A-A' (fig. 7) at depths ranging from 85 feet south of Amherst to 200 feet in the southeastern part of the county. The formation has a measured thickness of 99 feet in the outcrop in Bull Lake. The Kiamichi, which generally is easily identified, consists of gray to bluish-black shale, bluish-black paper shale, light-gray to brown fine- to medium-grained sandstone, light-gray nodular limestone, and sand and gravel. The shales generally are sandy or are interbedded with thin layers of flaggy sandstone.

The basal beds of the Kiamichi formation consist of coarse gravel that grades upward through a mixture of sand and gravel into a light-gray to brown coarse- to fine-grained sand and light-colored clay. The basal coarse-grained unit apparently thins in a northwest direction, as shown by reported thicknesses of 15 feet in well L-141, 10 feet in well K-11, and 6 feet in well K-2. The basal unit yields small quantities of rather highly mineralized water in the southern part of Lamb County.

The following section, measured from a point 2.5 feet above lake level on the west side of Bull Lake, includes part of both the Kiamichi formation and the Duck Creek formation of the Washita group.

	Thickness (feet)
Quaternary	
Duck Creek formation:	
12. Shale, brownish-yellow, unfossiliferous -----	6.8
11. Limestone, light-gray to yellow -----	.5
10. Shale, brownish-yellow; contains <u>Pervinquiera</u> sp. -----	8.6
Thickness of Duck Creek formation exposed -----	15.9
Kiamichi formation:	
9. Transition zone? Light-gray nodular limestone interbedded with blue-gray and buff shale; contains <u>Gryphaea corrugata</u> var. <u>tucumcarii</u> (Marcou) -----	12.6
8. Shale, bluish-black, weathers light gray -----	6.5
7. Covered -----	43.0
6. Limestone, light-gray, fossiliferous; contains <u>Exogyra texana</u> Roemer, <u>Gryphaea corrugata</u> Say, <u>Gryphaea corrugata</u> var. <u>tucumcarii</u> (Marcou), <u>Neitheia texana</u> (Roemer), interbedded with shale -----	2.2
5. Shale, brown to gray, unfossiliferous, interbedded with light-gray limestone -----	5.8
4. Shale, limy, weathers to light-gray, interbedded with buff-colored marl and sandstone stringer -----	7.3
3. Limestone, light-gray to brown, individual beds about 1.5 to 2.5 inches thick, interbedded with bluish-black paper shale -----	4.3
2. Shale, bluish-black, interbedded with light-gray sandstone -----	7.8
1. Limestone, light-gray, overlain by marl and shale, contains <u>Gryphaea navia</u> Hall, <u>Protocardia</u> cf. <u>P. multistriata</u> Shumard, <u>Neitheia</u> cf. <u>N. subalpina</u> (Bose), <u>Sphaera?</u> sp. -----	9.6
Thickness of Kiamichi formation exposed -----	99.1
Total thickness of section measured -----	115.0

WASHITA GROUP

Duck Creek formation. - The Washita group is represented in Lamb County by the Duck Creek formation, which crops out on the western margin of Bull Lake. At the outcrop the formation has a thickness of about 16 feet. Because of the lack of dependable well data and the indeterminate nature of the contact between the Duck Creek formation and the Kiamichi formation, it is not possible to say whether the Duck Creek is more extensively developed elsewhere in Lamb County. The Duck Creek consists of brownish-yellow shale and light-gray to yellow limestone. According to Brand (1953, p. 18), the contrast between the gray to bluish-black shale of the underlying Kiamichi formation and the lighter brownish-yellow shale of the Duck Creek formation is due to the change from a reducing environment during Kiamichi time to an oxidizing environment during Duck Creek time.

The Duck Creek formation is not a source of water supply in Lamb County.

TERTIARY SYSTEM

PLIOCENE SERIES

OGALLALA FORMATION

The Ogallala formation underlies all of Lamb County except the alkali lakes, where it has been removed by deflation. It crops out along the streams and on the western margins of the large alkali lakes. North and northeast of line A-A' (fig. 7) the Ogallala rests unconformably on the eroded surface of Triassic rocks, whereas south and southwest of the line it rests unconformably on Cretaceous rocks. The progressive thinning of the Ogallala southward, due to the presence of underlying Cretaceous rocks, is shown in figure 7. Although few wells in the northern part of the county completely penetrate the Ogallala formation, available data indicate that it has a thickness of more than 250 feet. In the extreme southern part of the county, its thickness is less than 100 feet.

The Ogallala formation is composed of fine to coarse sand, gravel, silt, red and yellow clay, and caliche. The sediments in general are unconsolidated and poorly sorted. The coarse sediments are most prominent in the lower part of the formation, whereas the finer grained sediments are most prominent in the upper part. It has been reported that in the vicinity of Littlefield the sands are cemented and of relatively low permeability and yield insufficient water for public-supply wells. In other areas, however, the finer grained sands are loose and subject to caving. The looseness of the fine-grained sands is shown by the radioactivity logs of test wells drilled in the sandhills. The increase in the radioactivity of the neutron curve opposite known water-bearing sand (pl. 2) is believed to be due to an increase in diameter of the bore hole as a result of the caving of the sand. Gamma-ray logs, drillers' logs, and pumping-test data indicate that the individual beds and lenses of sand, gravel, and clay of the Ogallala formation are not continuous over wide areas, but instead generally pinch out or grade laterally and vertically into finer or coarser materials (pl. 2).

In Lamb County, as in most of the High Plains, the Ogallala formation is the principal water-bearing formation. All the wells for irrigation, industry, and public supply obtain water from the Ogallala formation, and yields as high as 2,300 gpm have been measured. The water is very hard but is used for irrigation, and for domestic, industrial, stock, and public supplies throughout most of the county. However, in several localized areas in the southwestern part of the county and south of the sandhills, the water is too highly mineralized for most uses.

QUATERNARY SYSTEM

PLEISTOCENE SERIES

Rocks of Pleistocene age occur in the alkali lakes, in the stream valley of the North Fork of the Double Mountain Fork of the Brazos River, and in Running Water Draw.

The lake deposits generally crop out around the margins of Bull Lake and Illusion Lake except where they have been removed by erosion or where they are overlain by Recent dune deposits. They consist of bluish-gray calcareous and gypsiferous clay, light-gray sand, gravel, thin layers of white fresh-water limestone, and caliche. They lie unconformably on Pliocene and Cretaceous deposits. The lake deposits are probably not more than 75 feet thick.

Pleistocene stream deposits, which occur as valley fill in the large drainageways, consist of sand, gravel, silt, and clay. These deposits are below the level of the surface of the plains, and therefore they overlie Pliocene deposits and in turn are overlain by sediments of Recent age, which are darker in color.

The Pleistocene sediments, in general, lie above the water table and are not a source of water in Lamb County. However, because of the porous character of the sands and their position on the floor of the stream valleys, they serve as areas of recharge during periods of streamflow.

RECENT SERIES

Deposits of Recent age occur as sheets of windblown material, sand dunes, and valley fill. The windblown material mantles most of Lamb County and ranges in thickness from a featheredge to approximately 15 feet. The sand dunes form a belt approximately 8 miles wide extending across the center of the county (pl. 1). They generally form a superficial covering and are made up of actively migrating dunes and older, stabilized modified dunes. The active dunes are characterized by the typical dune topography, absence of vegetation, and a light-gray color, whereas the older dunes are characterized by a lower and rolling surface and a characteristic reddish-orange color, and they are anchored by vegetation. The dunes are not of great height; few are more than 40 feet high. Around the eastern and southeastern margins of Bull Lake, Illusion Lake, and Soda Lake the sand dunes are derived from material blown out of the lakes during prolonged dry periods. They are composed chiefly of grayish sand, but partly of silt and crystals of selenite (gypsum).

The valley-fill deposits of Recent age are in the channels of the intermittent streams in Lamb County and consist of buff-colored sand and gravel. In the North Fork of the Double Mountain Fork of the Brazos River about 8 miles south of the sandhills the deposits have recently filled the stream channel, covering a number of seeps that formerly issued at the surface.

Although the sediments of Recent age generally lie above the water table and yield no water to wells in Lamb County, they serve as catchment areas for rainfall and, therefore, aid in the recharge of the underlying formations.

CALICHE

Caliche, a secondary concentration of calcium carbonate, underlies most of Lamb County. It forms a resistant and prominent "cap rock," cropping out around the margins of Bull Lake and Illusion Lake, and along the stream valleys. It ranges in thickness from a featheredge to about 30 feet and consists principally of calcium carbonate, bands of secondary silica, and variable amounts of sand and clay. The caliche varies from a soft white chalky or powdery material to a hard mass. In places the caliche contains channels formed by the solvent action of percolating water. In the road cut north of Soda Lake the caliche has a coarse, platy texture and is strongly fractured and distorted. The distortion and fracturing are due, presumably, to volumetric expansion resulting from the introduction of excessive quantities of secondary calcium carbonate (West Texas Geol. Soc. and New Mexico Geol. Soc. 1949, p. 79). The caliche probably ranges in age from late Pliocene to Recent.

The caliche generally lies above the water table and, therefore, usually is not a source of water supply, in fact in some places the caliche impedes natural recharge because of its low permeability. According to Broadhurst (1938, p. 24), however, the caliche along the highway between Earth and the Bailey County line contained water. Since 1938 heavy withdrawal of ground water by pumping for irrigation has lowered the water table below the caliche in a part of this area.

GROUND WATER

OCCURRENCE

The amount of water that can be stored in rocks depends upon the pore spaces or voids. These voids range in size from very small pores in clay and silt to the large solution channels developed in caliche. The percentage of the total volume of the rock occupied by the voids determines the porosity of the rock. The size, shape, and arrangement of the openings determine the permeability of the rock, which is defined as the capacity of the rock to transmit water under hydraulic head.

Ground water moves slowly through the pore spaces in the rocks under the influence of gravity until it is discharged through wells, by seepage into streams, by evaporation and transpiration in stream valleys and ponds, or by subsurface movement from the county. The velocity at which the water moves is dependent in part on the hydraulic gradient or slope of the water table which, in Lamb County, conforms in general to the southeastward-sloping land surface. Although the slope of the water table varies from place to place, owing to the topography and local variations of recharge or discharge, the average slope is about 10 feet to the mile. Taking into consideration both the permeability and the porosity the normal rate of ground-water movement is estimated to be somewhat less than 200 feet a year.

Ground water in Lamb County is obtained from the sand and gravel of the Ogallala formation, the partly cemented basal sand and gravel of the Cretaceous rocks, and the caliche. The water in the Ogallala formation, which is the principal aquifer in Lamb County, is generally unconfined (under water-table conditions). However, owing to the lenticular character of the Ogallala, the water locally may be under sufficient hydrostatic pressure to rise in the well a short distance above the top of the water-bearing bed.

RECHARGE

NATURAL RECHARGE

The source of the ground water in Lamb County is precipitation within the county and in areas of the High Plains to the northwest. Most of the precipitation is lost through evaporation and transpiration by crops and shrubs, but a small part of that which enters the soil moves downward past the root zone to recharge the underground reservoirs by direct infiltration. Some of the precipitation runs off into streams and ponds and a part of this also seeps down to the water table eventually.

The rate and amount of recharge are difficult to determine, owing to wide variations in, as well as lack of information on, the permeability and storage capacity of the rocks from place to place, the amount and intensity of rainfall, and the rates of evaporation and transpiration. However, studies on the High Plains (Theis, Burleigh, and Waite, 1935, p. 2; White, Broadhurst, and Lang, 1946) indicate that, of the average annual precipitation of about 18 inches, only a small fraction of an inch recharges the underground reservoir.

The principal areas of infiltration are the sandy soils of the shallow-water area (grid A, pl. 1), sand dunes, depression ponds, and streams. Although the surficial deposits that mantle the county are sandy, the depth to water is generally fairly great and most of the precipitation that falls as light rains is held by the soil and later evaporated or transpired. Recharge by direct infiltration through the soil zone is limited to periods of exceptionally heavy precipitation. Such recharge is shown by the large rise of water levels in wells in grid A during 1941 and 1942. During that time about 65 inches of precipitation fell in Muleshoe, causing an average net rise of water level of about 8 feet in 9 observation wells. During the same period, however, water levels rose considerably less in the northeastern part of the county, where the soil is tighter and the depth to water greater.

The most favorable area for recharge in Lamb County is in the sandhills extending east-west across the north-central part of the county. Because of the high porosity and permeability of the sand dunes, nearly all the precipitation that falls in the dune area is rapidly absorbed, and consequently little or no surface drainage has been developed. In places the downward movement of water is probably hindered somewhat by the less permeable caliche layer underlying the sandhills. However, the caliche may contain solution channels that permit the fairly rapid movement of water down to the water table.

The average annual recharge in the sandhill area is not known. Figure 8 shows, however, the effect of recharge after the heavy rainfall in 1941, when about 44 inches of precipitation fell at Muleshoe. As a result of this rainfall, water levels in the sandhill area showed a considerable rise, reaching a maximum of 6 feet in well F-13.

Shallow depressions or sinks, ranging in depth from a few feet to more than 50 feet and in diameter from a few hundred feet to a mile or more, are common in Lamb County. They average nearly one per square mile. Storm water that collects in these basins after heavy rains forms temporary lakes, which in the southern part of the county may disappear in a short time, or in the northern part of the county may remain for months. Auger-hole records obtained by Broadhurst (1938) in Lamb County, and studies made by White, Broadhurst, and Lang (1946) in other areas on the High Plains, showed that in some depressions little or no caliche is present, in others relatively soft caliche is found, and in still others very dense caliche is encountered. The bottoms of most of the depressions in Lamb County are covered with deposits of silt and clay which are extensively fractured by desiccation cracks. The cracks provide a passage for the rapid initial downward movement of water, but continued percolation is slowed or stopped as the clay swells, sealing the cracks.

Water-level measurements in wells in depression ponds, or nearby wells, in other areas on the High Plains indicate that a substantial part of the recharge to the underground reservoir is derived from the infiltration of water that collects in the depressions. For example, the water-level measurements obtained from automatic water-stage recorders on two wells in Floyd County, where conditions are similar to those in Lamb County, showed rapid response to the recharge from water accumulated in the depression after heavy rains in July 1950. The water levels continued to rise for more than a year as additional runoff accumulated in the pond. The resulting local mound on the water table was not fully dissipated by lateral movement of the water until October 1951.

Recharge of the ground-water reservoir from streamflow is small during periods of normal rainfall, owing to the small drainage area of the streams. After exceptionally heavy rains, however, the intermittent streams in Lamb County carry large quantities of water, of which much is lost by downward percolation to the water table before reaching the county line. Local residents reported that after the heavy rains in 1941 water in the North Fork of the Double Mountain Fork of the Brazos River flowed across the highway south of Earth, but did not flow completely across the sandhills. Although a large part of the water was lost to the ground-water reservoir during its flow through the sandhills, a part of the water was able to reach the area north of the sandhills and percolate down through the stream bed there.

ARTIFICIAL RECHARGE

In the past few years several attempts have been made in the High Plains to increase the rate of recharge by artificial means, and to reduce the amount of water lost from the depression ponds through evaporation. The three methods tried in Lamb County include the single-purpose drainage well, the dual-purpose well, and the drainage trench.

In 1951 the city of Littlefield drilled a well to drain the city part of accumulated storm runoff. The well, 93 feet deep, was cased and filled with sand and gravel to filter the water before it entered the aquifer. Although the well has not been thoroughly tested, results of similar experiments in other parts of the High Plains indicate that wells of this type soon become clogged with silt.

An effort to remedy the silting problem of the single-purpose drainage well resulted in the development of the dual-purpose well. Well G-191 was drilled in 1951 to a depth of 180 feet. It is a 16-inch well with a dual-purpose pump, which can pump water through a closed pipe system for irrigation during dry periods, and can also pump out the sediment deposited on the well face by the injected pond water. The pond water is injected by gravity flow down the annular space between the pump column and casing. Owing to the lack of sufficient pond water during 1951 and 1952, the

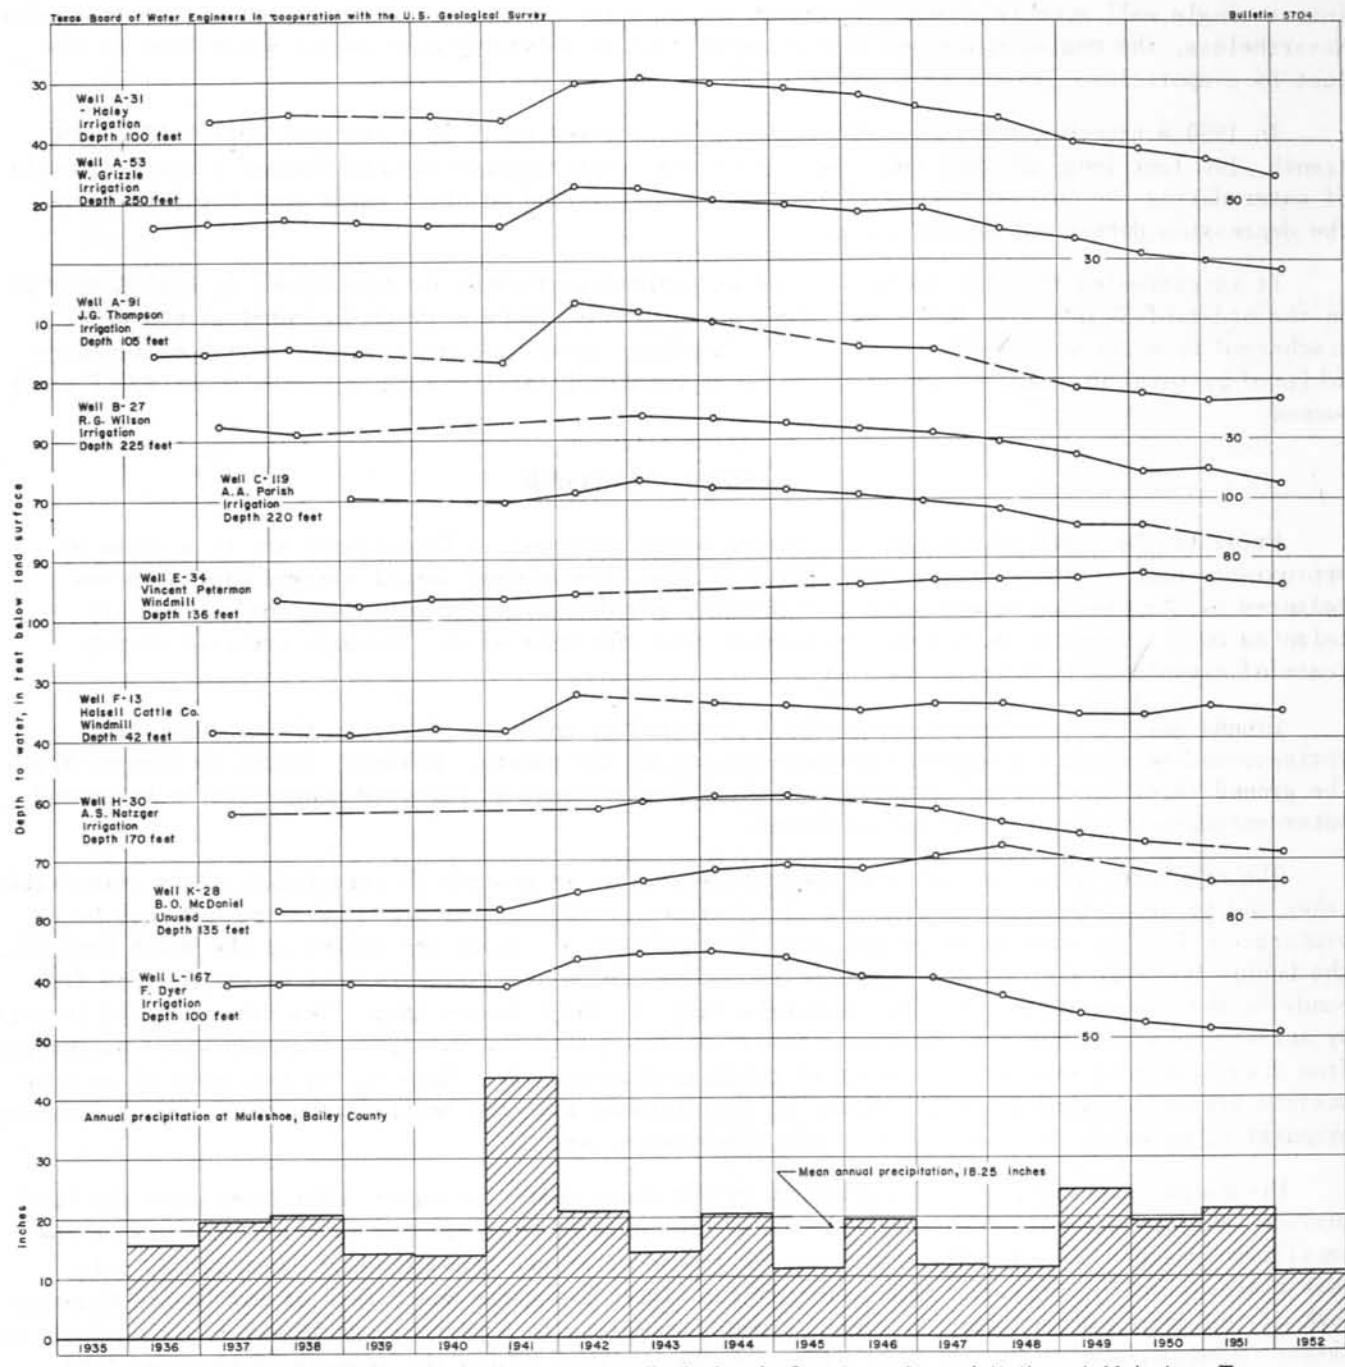

FIGURE 8.-Hydrographs of 10 observation wells in Lamb County and precipitation at Muleshoe, Tex.

success of this dual-purpose well has not been determined. It is probable, however, that one of the larger depressions—that is, one containing more than about 40 acre-feet of water—cannot be drained into a single well quickly enough to prevent the drowning of crops in a large part of the depression. Nevertheless, the dual-purpose well may be successful in salvaging some of the water that is now lost by evaporation.

In 1950 a trench was dug in a depression which covered about 20 acres near well C-190. The trench, 100 feet long, 50 feet wide, and 6 feet deep, was reported to have drained a small quantity of water during the initial period of drainage, but it failed to drain water that accumulated in the depression during subsequent rains.

It is estimated that the average annual accumulation of water in depressions in Lamb County is on the order of 30,000 acre-feet, equivalent to only about 15 percent of the total ground water discharged by wells in Lamb County in 1950. Therefore it is apparent that the amount of recharge achieved by total drainage of the ponds would be relatively small compared to the quantity of water pumped.

NATURAL DISCHARGE

Prior to the start of pumping, the ground-water reservoir in Lamb County was in a state of approximate equilibrium. Over a long period of time, the average annual natural discharge was balanced by the average annual natural recharge. The discharge, however, was not necessarily balanced by the recharge during any particular year, for most of the recharge occurred during years of exceptionally heavy precipitation.

Ground water is discharged naturally by evaporation and transpiration, through seeps and springs, and subsurface movement southeastward out of the county. However, it may be assumed that the ground water discharging naturally by subsurface movement is balanced approximately by ground water entering the county from the northwest.

The discharge of ground water by evapotranspiration in general is restricted to the water-table lakes and to areas where the water table is near the surface of the land. Most of the loss by evaporation is from such areas in and near the sandhills and along the valley of the North Fork of the Double Mountain Fork of the Brazos River. Some ground water also is lost by evaporation from ponds in the stream valley and from Bull Lake (fig. 9) and Illusion Lake. The lakes are fed in part by surface runoff and in part by ground water, and therefore the quantity of ground water discharged from these lakes by evaporation cannot be determined accurately. However, on the basis of an open surface area of approximately 500 acres, it is estimated that the total discharge of ground water by evaporation probably does not exceed 2,500 acre-feet a year.

Discharge by transpiration is greatest in the areas where the water table intersects the land surface, where the capillary fringe extends to the surface, or where the root zone extends to the capillary fringe. Considerable quantities of ground water are transpired by marsh grass, tule, salt grass, alfalfa, and other plants in several places along the North Fork of the Double Mountain Fork of the Brazos River, from the Bailey-Lamb County line to a point about 15 miles south of the sandhills. A comparison of the acreage covered by these plants during the summers of 1939 and 1950 indicates that the loss of ground water by transpiration in the eastern part of the stream valley decreased owing to a decline in the water table below the limits of root penetration.

The quantity of water used by plants varies according to the species and the density of growth. White, Broadhurst, and Lang (1946, p. 391) estimated that marsh grass and sedges use the most water per acre, and that they are followed in order by subirrigated alfalfa, salt grass, and meadow grass. The annual consumption of water per acre by these plants was estimated to range from 0.5 acre-foot to 3 acre-feet. It is estimated that the consumption of ground water by plants in Lamb County is about 2,000 acre-feet a year; thus, the total natural discharge by evapotranspiration probably is about 4,500 acre-feet a year.

FIGURE 9.- Bull Lake, Lamb County, Tex., showing caliche and rocks of Cretaceous age in foreground.

In addition to those along the North Fork, springs occur in the large lakes where the land surface intersects the water table. Bull Lake and Illusion Lake are fed in part by such springs. The yields of the springs are not large enough to be measured, and most of the ground-water flow into the lakes probably takes place through the underlying Quaternary lake sediments rather than through springs appearing at the surface.

Springs form small pools and ponds in the stream valley of the North Fork of the Double Mountain Fork of the Brazos River from the sandhills to a point about 7 miles south of the sandhills. Although the discharge from any one spring is too small to be measured, the aggregate discharge from a group of springs at times results in surface flow. In May 1952, the flow of a group of springs (F-145) was about 75 gpm; in August and in November 1952, no streamflow was observed, although most of the ponds formed by the springs were still present. Some of the water discharged from the ground-water reservoir by springs during the winter and spring months, when evaporation is low, re-enters the ground before it reaches the Lamb-Hale County line. Thus, such water is not actually part of the ground water that is lost by natural discharge in Lamb County.

DEVELOPMENT

The early ranchers in Lamb County obtained water from the springs and water-table ponds. Prior to 1913, ground water was used only for stock and domestic needs. The first irrigation well of record (well A-37) was drilled in 1913 in the northwestern part of the county. The early wells, many of which were hand dug, were shallow and used low-speed centrifugal pumps powered by oil-burning units. The development of ground water for irrigation was only moderately successful because of the high operating costs and low efficiencies of the pumps and powerplants. During the 25-year period 1913 to 1937, inclusive, about 75 wells were drilled, most of which were in the northwestern and southeastern parts of the county. From 1938 to 1946, inclusive, the number of irrigation wells increased slowly but steadily (fig. 10), owing to the introduction of high-speed deep-well turbine pumps powered by small automobile engines with direct drive. Since 1947, however, the number of wells in operation has more than doubled, and the total number of irrigation wells as of the end of 1950 was about 1,700. It is estimated that during the 2-year period 1951-52 approximately 250 additional wells were drilled.

The use of ground water in Lamb County has increased each year since 1938, except 1941, 1942, and 1949 when rainfall was above normal and irrigation requirements were light. It is estimated that in 1938 approximately 17,000 acre-feet of water was pumped for irrigation, as compared to 200,000 acre-feet in 1950 (table 3).

Table 3.- Irrigation wells in Lamb County

Year	Number of wells	Pumpage, in acre-feet	Acres irrigated
1947	900	115,000	110,000
1948	1,250	155,000	150,000
1949	1,475	145,000	180,000
1950	1,700	200,000	210,000
1951	1,825	210,000	220,000
1952	1,950	300,000	230,000

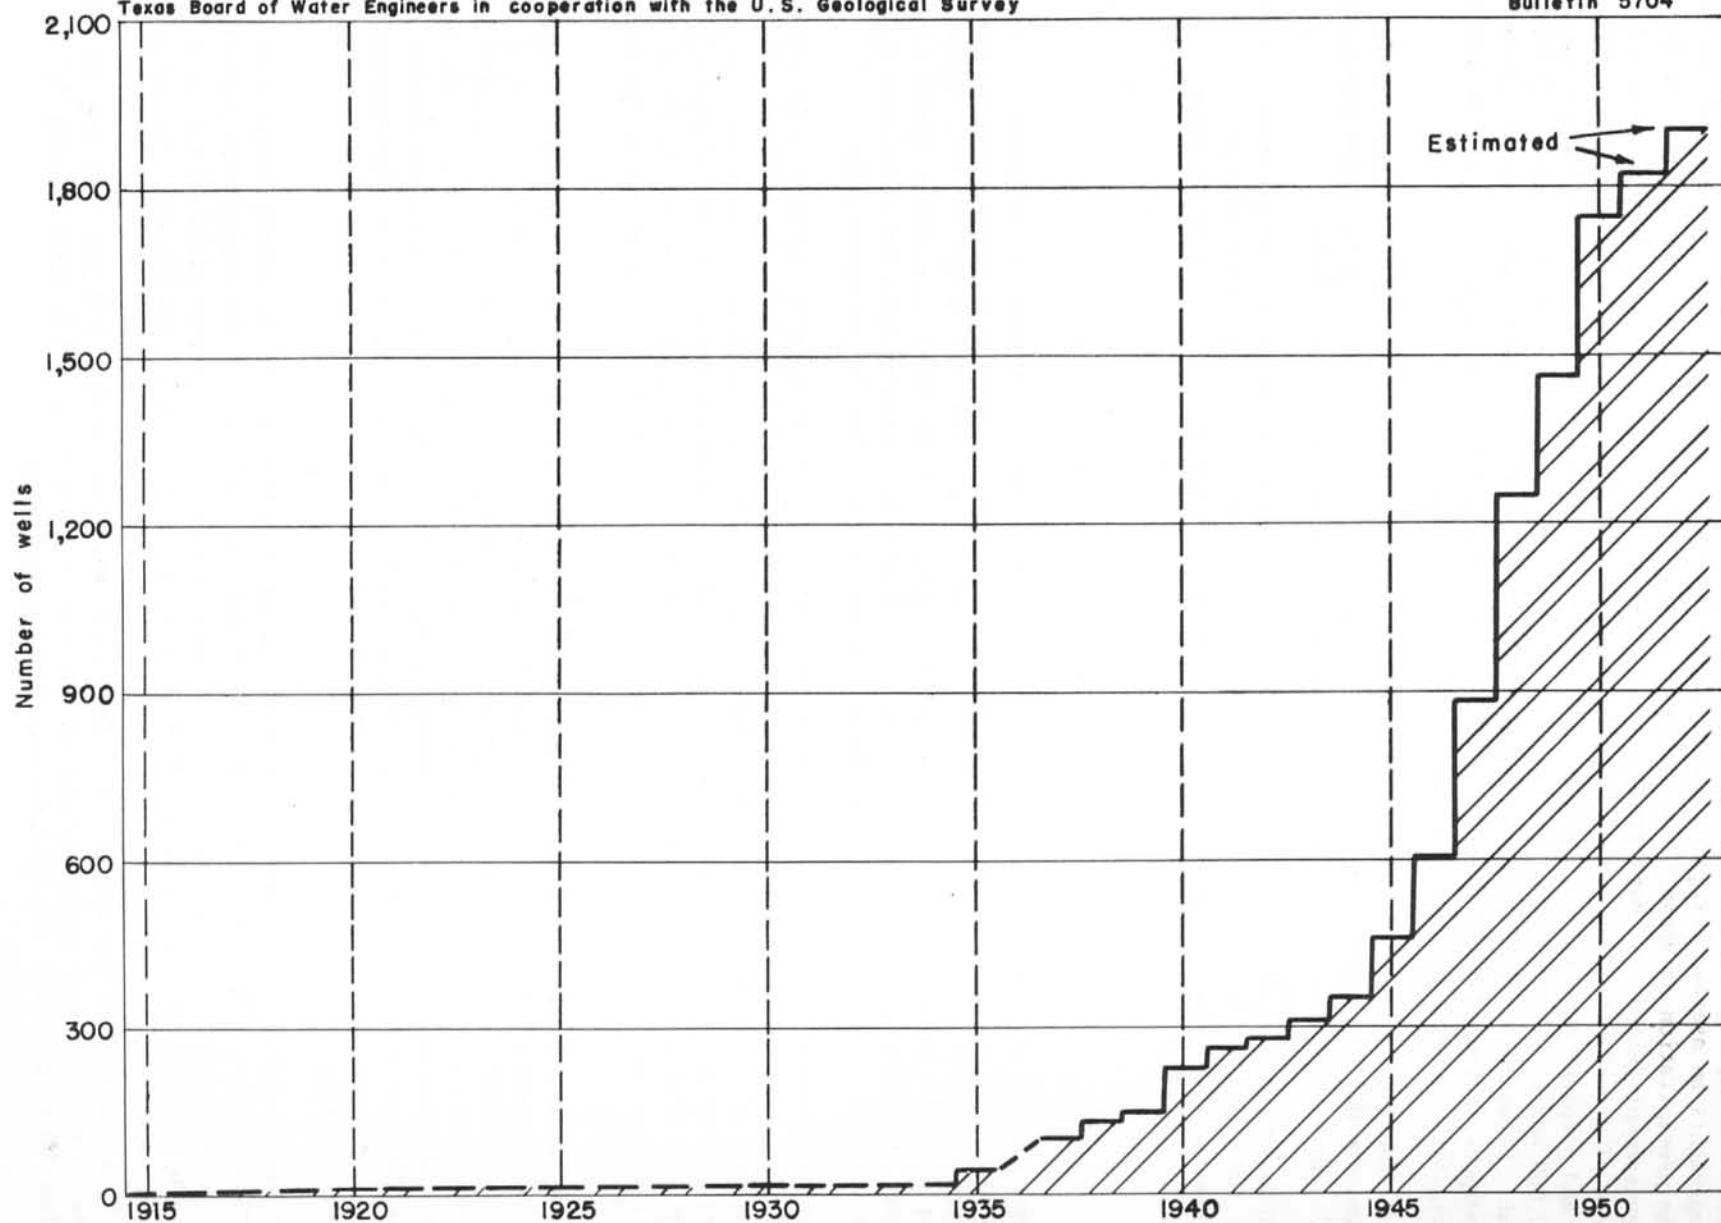

FIGURE 10.-Approximate number of irrigation wells in operation in Lamb County, 1915-52.

Approximately 120 acre-feet of water per well is pumped for irrigation during an average year. This represents an average irrigation requirement of about 1.0 foot per acre. However, during years when the precipitation is above normal or is distributed unusually well for crop growth, the irrigation requirement decreases. For example, during 1948, when rainfall was below normal, about 155,000 acre-feet of ground water was pumped for 150,000 acres, whereas in 1949, when rainfall was above normal and preplanting moisture was high, only about 145,000 acre-feet of ground water was pumped for 180,000 acres. This represents a decrease in the irrigation requirement from about 1.0 foot to 0.8 foot. Because rainfall was below normal during 1952, when 10.44 inches was recorded, ground-water pumpage increased by 90,000 acre-feet over the 210,000 acre-feet pumped in 1951. As a result, the irrigation requirement increased from 0.9 foot to 1.5 feet.

The annual use of ground water for domestic, industrial, and public supply in Lamb County is approximately 0.13 acre-foot per capita, or approximately 2,600 acre-feet for the total population in 1950. This represents less than 2 percent of the total pumpage in the county.

The county may be divided conveniently into three distinct areas based upon prominent physiographic features; the northern part of the county, the southern part, and the sandhills. The development and hydrologic properties of the ground-water reservoir in each of these areas are discussed briefly below.

NORTHERN PART OF THE COUNTY

Approximately 40 percent of the wells used for irrigation in 1950 were in the northern part of the county, which includes all the area north of the sandhills. Broadhurst (1938) reported that 47 wells were in operation in the area in 1937. Of these, 32 were near the sandhills where the depth to water was relatively shallow. As more efficient pumps were developed, irrigation spread northward where the depth to water is greater. By the end of 1950, approximately 700 wells were fairly uniformly distributed over the area, averaging approximately 2.3 wells per square mile.

Figure 11 shows the depth to water in wells in October 1951 by means of isobath lines (lines of equal depth to water). The depth to water ranges from more than 100 feet in the north-central and eastern parts of the area to less than 15 feet in the western part, although in most wells it ranges from about 80 to 100 feet. The slope of the water table is southeastward at a rate of about 10 feet per mile. In grid A, where the depth to water is slight, the wells range in depth from 65 to 250 feet and average about 140 feet, whereas in grid D the wells range in depth from 160 to 300 feet and average 210 feet.

The saturated thickness of the Ogallala formation in the northern part of the county is shown in figure 7. In general, the saturated thickness is fairly uniform, though it decreases slightly toward the east. Few wells penetrate the entire thickness of the Ogallala and therefore the maximum thickness of the saturated part of the formation is not known. Well B-47 entered the Triassic red beds at 225 feet and penetrated 136 feet of saturated material. Well A-53, however, which was drilled to a depth of 250 feet without encountering the Triassic rocks, penetrated 226 feet of saturated material. It is believed that the latter figure is about the maximum saturated thickness of the Ogallala formation in Lamb County.

The measured yields of 53 irrigation wells in the northern part of the county ranged from 515 to 2,240 gpm and averaged 980 gpm. The largest discharges in that part of the county were obtained from wells in grid A, and in general the yields decreased eastward. The average yield of 8 wells in grid A was 1,390 gpm, and the average yield of 45 wells in grids B, C, and D was 900 gpm. The specific capacities (discharge in gallons a minute per foot of drawdown) of 17 wells ranged from 79 in well A-87 to 27 in well C-124 and averaged 46. In grid A, where the pumping lift was less than 60 feet, the specific capacities of wells averaged 62, whereas in grids B, C, and D, where pumping lifts ranged from 90 to 135 feet, the specific capacities averaged 40.

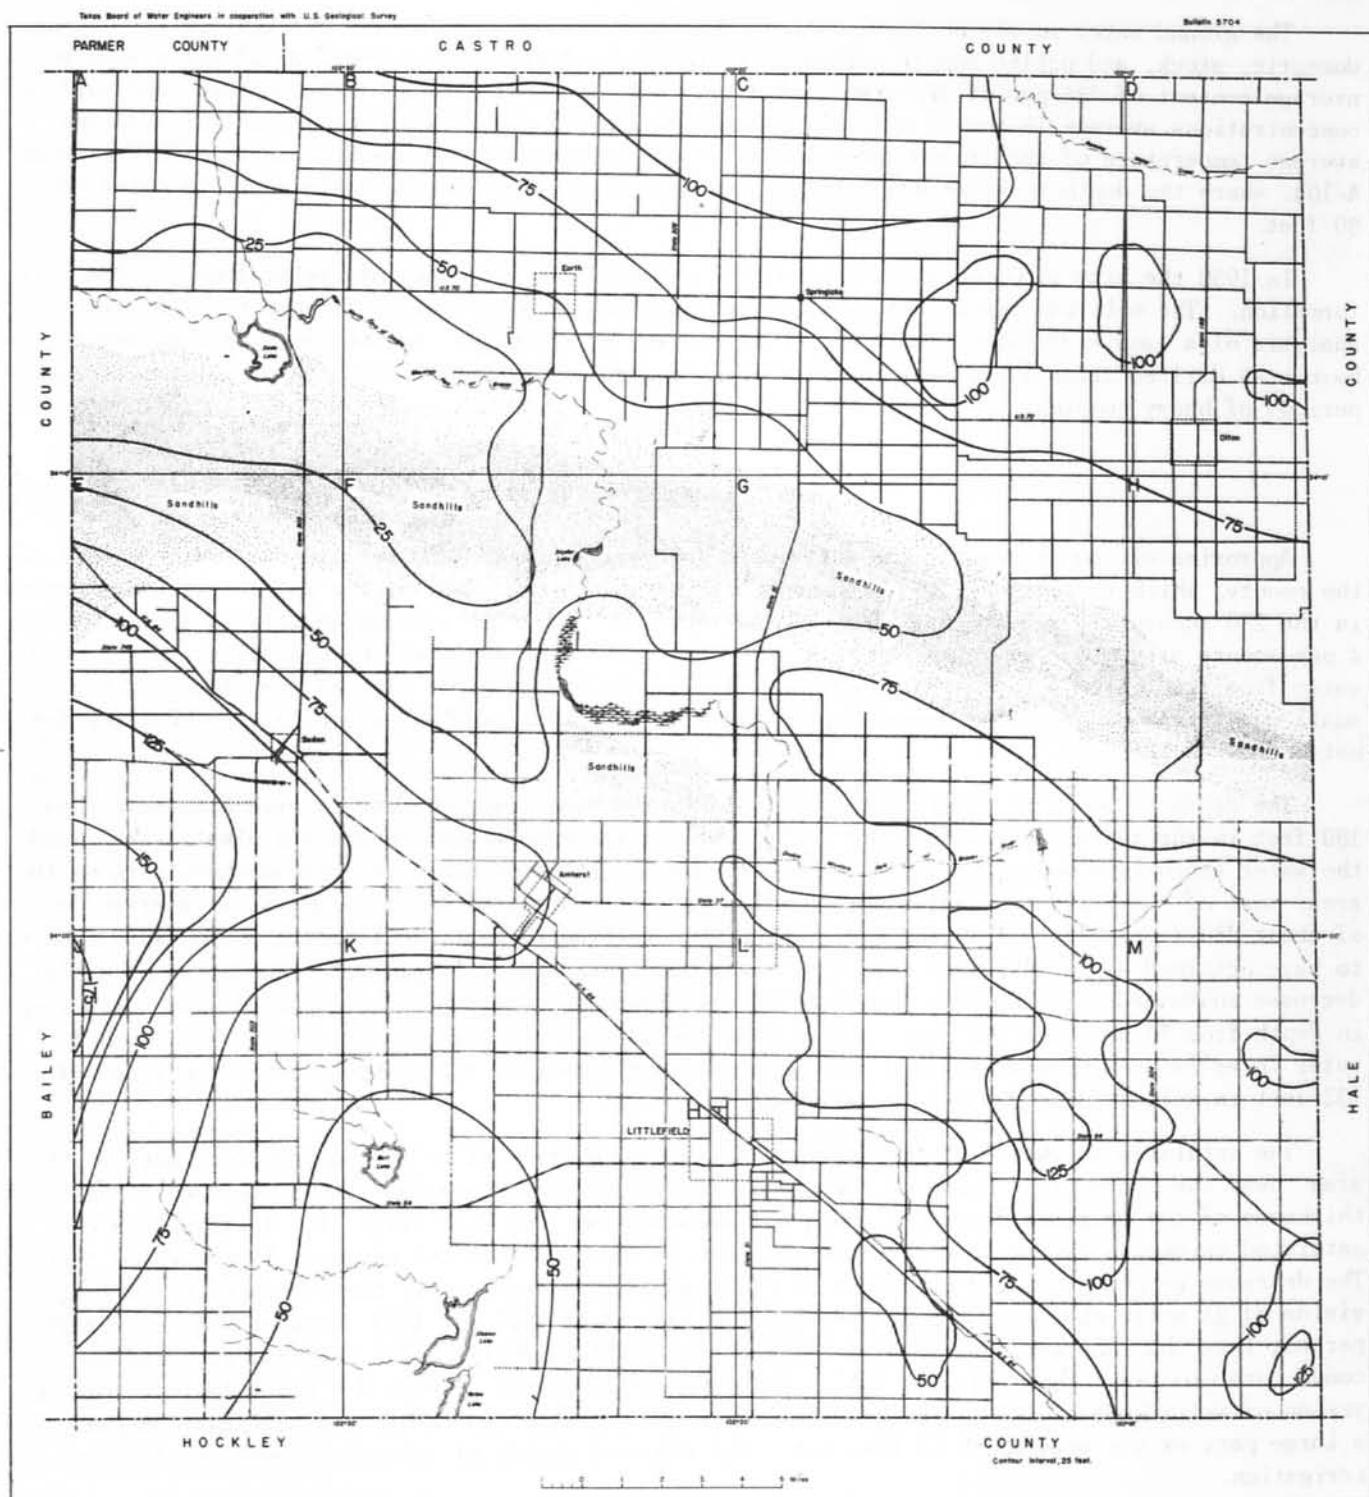

FIGURE II.-Depth to water in Lamb County, October 1951.

The ground water in the northern part of the county is of satisfactory quality for irrigation, domestic, stock, and public supply, although it is hard. Analyses of water from 23 wells show an average content of 336 ppm of dissolved solids and a hardness of 236 ppm. The chloride and sulfate concentrations average 19 and 32 ppm. In 14 wells uniformly distributed throughout the area the average temperature of the ground water was 63°F and the range of temperature was from 59°F in well A-104, where the depth to water was 5.5 feet, to 64°F in well D-132, where the depth to water was 80 feet.

In 1950 the city of Olton was supplied from well D-232, which obtained water from the Ogallala formation. The well was reported to be 200 feet deep and to have yielded 250 gpm in 1946. The analysis of a sample of water from well D-232 is given in table 11. Another well is reported to have been drilled recently to meet the increasing demand on the public water-supply system during periods of heavy pumping.

SOUTHERN PART OF THE COUNTY

Approximately 60 percent of the wells used for irrigation in 1950 were in the southern part of the county, which includes all the area south of the sandhills. Most of the wells were concentrated in the 230 square miles northeast of line A-A' (fig. 7) and their average density in this area was 4 per square mile. On January 1, 1951, about 1,000 wells were equipped for operation and all drew water from the Ogallala formation. Several wells in the southwestern part of the area obtained small quantities of water for domestic purposes from the basal sand and gravel of the Kiamichi formation.

The depth to water in wells in the Ogallala ranges from about 40 feet in grid E to more than 180 feet in the western part of grid J. The depth to water decreases toward the alkali lakes, and the water table intersects the surface at Bull Lake and Illusion Lake. In the northern part of the area, most of the irrigation wells were drilled to the red beds of Triassic age at an average depth of about 230 feet. Wells J-10 and K-67, which were drilled to test the Triassic rocks, were reported to have obtained an insufficient supply of water for irrigation. In general, the depths of wells decrease southward. In the area underlain by Cretaceous sedimentary rocks, however, the wells range in depth from 80 to about 600 feet, though most are between 120 and 150 feet deep. The depth to water in wells obtaining water from the basal sand and gravel of the Kiamichi formation ranges from 233 feet in well J-23 to 20 feet in well K-84.

The saturated thickness of the Ogallala formation is greatest in the northwestern part of the area, near the sandhills. Owing to the presence of underlying Cretaceous rocks, the saturated thickness of the Ogallala decreases south and southwest of line A-A' (fig. 7). In this area the saturated thickness ranges from less than 25 feet to about 80 feet and averages less than 50 feet. The decrease in the saturated thickness is accompanied by a decrease in the yields of wells. The yields of 21 wells that were measured during the summers of 1951 and 1952 averaged 755 gpm, or 23 percent less than the average yield of wells north of the sandhills. The decrease in yield becomes more prominent south of line A-A'. For example, the yield of well H-9 was 1,260 gpm, but the yields of wells K-56 and K-58, in the area underlain by Cretaceous rocks, were 151 and 136 gpm. In a large part of the area south of line A-A', the reported yields of wells have been insufficient for irrigation.

The quality of ground water in the area south of the sandhills is generally suitable for most purposes. However, the chemical analyses of water from 57 wells show that the ground water is highly mineralized near the alkali lakes and in a localized area in grids G and L.

In the southwestern part of the county (grids J and K), the quality of the ground water is affected by the presence of Bull and Illusion Lakes (fig. 9), which are bottomed below the water table in the Ogallala formation. These alkali lakes are fed in part by surface runoff from a large drainage area, and in part by springs that issue from the Ogallala; thus they contain water except during prolonged periods of drought. There is no surface drainage from the alkali lakes, and therefore the concentration of mineral matter in the water is increased by evaporation, and during very dry periods salts are precipitated. An analysis of a sample of water from Bull Lake (K-87) shows 19,000 ppm of dissolved solids, 3,860 parts of sulfate, and 8,500 parts of chloride. During periods of heavy rainfall, the salts that have been precipitated previously in the basin are redissolved and carried back into the Ogallala.

Analyses of water from wells K-82 to K-85, which draw from the Cretaceous rocks north of Bull Lake, indicate a high degree of mineralization. These analyses show an average of 2,830 ppm of dissolved solids, 1,140 parts of sulfate, and 630 parts of chloride. It is probable that the highly mineralized water north of Bull Lake is from the basal sands of the Cretaceous, in which there is less circulation of water than in the Ogallala. In contrast to the alkali lakes, the more numerous shallower basins are bottomed above the water table and serve as areas of ground-water recharge. The water that is added to the reservoir through these depressions is less mineralized than the average ground water in the Ogallala formation.

Highly mineralized water occurs in a localized area in grids G and L, about 2 miles south of the North Fork of the Double Mountain Fork of the Brazos River. This mineralization is the result of the concentration of mineral content by evaporation of water from the area of springs shown in plate 1. The analysis of a sample of water from this area (fig. 12) showed 2,840 ppm dissolved solids, 1,130 parts of sulfate, and 470 parts of chloride. The water remains as spring flow for only a short time before it returns to the ground-water reservoir and moves down the gradient. The analyses of water from two wells (L-8 and L-15) showed an average of 3,920 ppm of dissolved solids, 1,720 parts of sulfate, and 740 parts of chloride. Part of the dissolved mineral content of the ground water in this area may be due to the movement of water from an area of springs that formerly were in the North Fork of the Double Mountain Fork of the Brazos River east of the present area of springs, but that have disappeared recently owing to a general lowering of the water table.

In 1951 the city of Littlefield was supplied from five wells (L-105, L-135, L-138-40), which obtained water from the Ogallala formation. The wells ranged from 130 to 240 feet in depth and were reported to yield 400 to 600 gpm when drilled.

The annual pumpage from the municipal wells during the 10 years 1942 to 1951, inclusive is given in table 4.

Table 4.- Annual pumpage for the city of Littlefield, 1942-51

Calendar year	Pumpage (millions of gallons)
1942	105.4
1943	131.0
1944	131.5
1945	143.1
1946	174.1
1947	217.2
1948	238.8
1949	228.1
1950	275.3
1951	339.1

FIGURE 12.- Springs in valley of North Fork of Double Mountain Fork of Brazos River.

The results of analyses of composite samples of water from wells L-139 and L-140 are given in table 5.

Table 5.- Chemical analyses of water from Littlefield municipal wells (composite samples from wells L-139 and L-140)

	October 6, 1937 (ppm)	March 1, 1945 (ppm)
Silica (SiO_2)	--	42
Iron (Fe)	--	.04
Calcium (Ca)	61	62
Magnesium (Mg)	41	39
Sodium and potassium (Na + K)	60	60
Bicarbonate (HCO_3)	310	303
Sulfate (SO_4)	81	77
Chloride (Cl)	74	69
Fluoride (F)	--	2.0
Nitrate (NO_3)	--	1.8
Dissolved solids	--	502
Hardness as CaCO_3	321	315
pH	--	7.7

The cities of Amherst and Sudan obtain water from 2 and 5 wells, respectively, which tap the Ogallala formation. The saturated thickness of the Ogallala at Amherst is considerably greater than at Sudan. The yields of the wells vary correspondingly, averaging 250 gpm at Amherst and 40 gpm at Sudan. The average daily pumpage reported in 1948 was 150,000 gallons at Amherst and 100,000 gallons at Sudan. The results of analyses of water from wells at these two cities are given in table 11.

SANDHILLS

The sandhills cover an area of about 150 square miles (pl. 1) extending in a belt across the northern part of Lamb County. Because of the sandy soil and dune topography (fig. 13), the area is generally unsuitable for agricultural purposes except the raising of livestock. Since June 1952, however, an increasing amount of ground water has been withdrawn for the electrical generating plant south of Earth.

The depth to water in wells ranges from about 8 feet in the western part of the sandhills to 71 feet in the eastern part. However, where the North Fork of the Double Mountain Fork of the Brazos River has cut through the sandhills, the stream channel intersects the water table to form water-table ponds such as Snyder Lake. In the western part of the sandhills, wind action has formed shallow depressions which expose the water table during periods of low evaporation.

Most of the wells in the sandhills supply water for stock and do not completely penetrate the saturated thickness of the Ogallala formation. The logs of 12 test wells and 6 industrial wells in grids B and F indicate that the saturated thickness is about 175 feet; but it is believed that the saturated thickness decreases eastward. The slope of the water table and, consequently, the direction of movement of the ground water are, in general, southeastward, but irregularities occur in localized areas. Plate 2 shows a mound on the water table at well B-165, which possibly indicates recharge to the ground-water reservoir from the nearby stream.

FIGURE 13.- Sand dune in sandhills, Lamb County, Tex.

Based on pumping tests of about 8-hour duration, the yields of 12 wells in the plant "X" area in grids B and F ranged from 720 to 1,100 gallons a minute. The drawdown in five of these wells averaged 25.2 feet, and the specific capacities averaged 39, ranging from 26 to 50 gpm for each foot of drawdown. The specific capacities of wells B-170 and F-142 after they were pumped 24 hours were 56 and 39.5, respectively.

Ground water in the sandhills is suitable for irrigation, stock, and domestic uses, but it may require softening for industrial use. The analyses of water from nine wells indicate that the dissolved mineral content decreases eastward. For example, samples of water from wells F-13, F-140, and F-142 show an average of 670 ppm of dissolved solids, 95 parts of sulfate, and 56 parts of chloride; whereas water from well G-38 shows 360 parts of dissolved solids, 24 parts of sulfate, and 10 parts of chloride. The relatively high mineral content of the ground water in the western part of the sandhills is due to evaporation from numerous seeps and water-table ponds, whereas in the eastern part seeps and ponds are absent. The mineral content of the water in the seeps and ponds is increased by evaporation, and subsequent movement of the mineralized water down the hydraulic slope contaminates the ground water in other areas. A sample of water from Soda Lake (A-106) contained 31,400 ppm of dissolved solids, 14,500 parts of sulfate, and 7,310 parts of chloride, and a sample of water from well A-107, about half a mile south of Soda Lake, contained 1,370 parts of dissolved solids, 437 parts of sulfate, and 218 parts of chloride.

In April 1952, a 24-hour pumping test was made on well F-142 in the sandhills, to determine the hydrologic properties of the Ogallala formation. The well was pumped at the rate, according to the meter, of 887 gpm, and the depth to water was measured in the pumped well and two observation wells, F-2 and B-166, by hand tape and automatic water-stage recorders. Drawdown curves were plotted for wells F-2 and F-142 (fig. 14). At the end of a 24-hour period of pumping, the drawdown in well F-142 was 15.9 feet; in well F-2, at a distance of 462 feet, the drawdown was 2.53 feet, and in well B-166, at a distance of 3,200 feet, it was imperceptible. After the pump was shut down, recovery measurements were made for a period of 24 hours (fig. 14).

In November 1952, a 27-hour test was run on well B-170 to check the results obtained from the test of April 1952. Well B-170 was pumped for 39 hours at the rate of 790 gpm and the depth to water in the pumped well and in well B-167, 401 feet distant, was measured at frequent intervals. The drawdown and recovery curves are shown in figure 15.

The data obtained from these tests were analyzed by means of the nonequilibrium formula, developed by Theis (1935) and modified by Jacob (1946), to determine the coefficients of transmissibility and storage of the water-bearing formation. The nonequilibrium formula assumes that the water-bearing formation is infinite in areal extent, that it is homogeneous and isotropic (conducts water in all directions with equal facility), that its transmissibility is everywhere the same, that the coefficient of storage is constant, and that water is released from storage instantaneously with a decline in head. Although field conditions do not conform strictly to these assumptions, the figures obtained for the coefficients of transmissibility and storage are still of considerable value in interpreting the water-bearing characteristics of the formation.

The coefficient of transmissibility may be expressed as the quantity of water, in gallons a day, that will flow through a vertical strip of the water-bearing material 1 mile wide under a hydraulic gradient of 1 foot per mile. Thus, the quantity of water that will flow each day through each mile of the water-bearing material is the product of the coefficient of transmissibility and the existing hydraulic gradient. The storage coefficient is defined as the volume of water released from or taken into storage per unit surface area of the aquifer per unit change in the component of head normal to that surface. Under water-table conditions the coefficient of storage is essentially equivalent to the specific yield of the aquifer, which is defined as the ratio of the volume of water which, after being saturated, the aquifer will yield by gravity to its own volume.

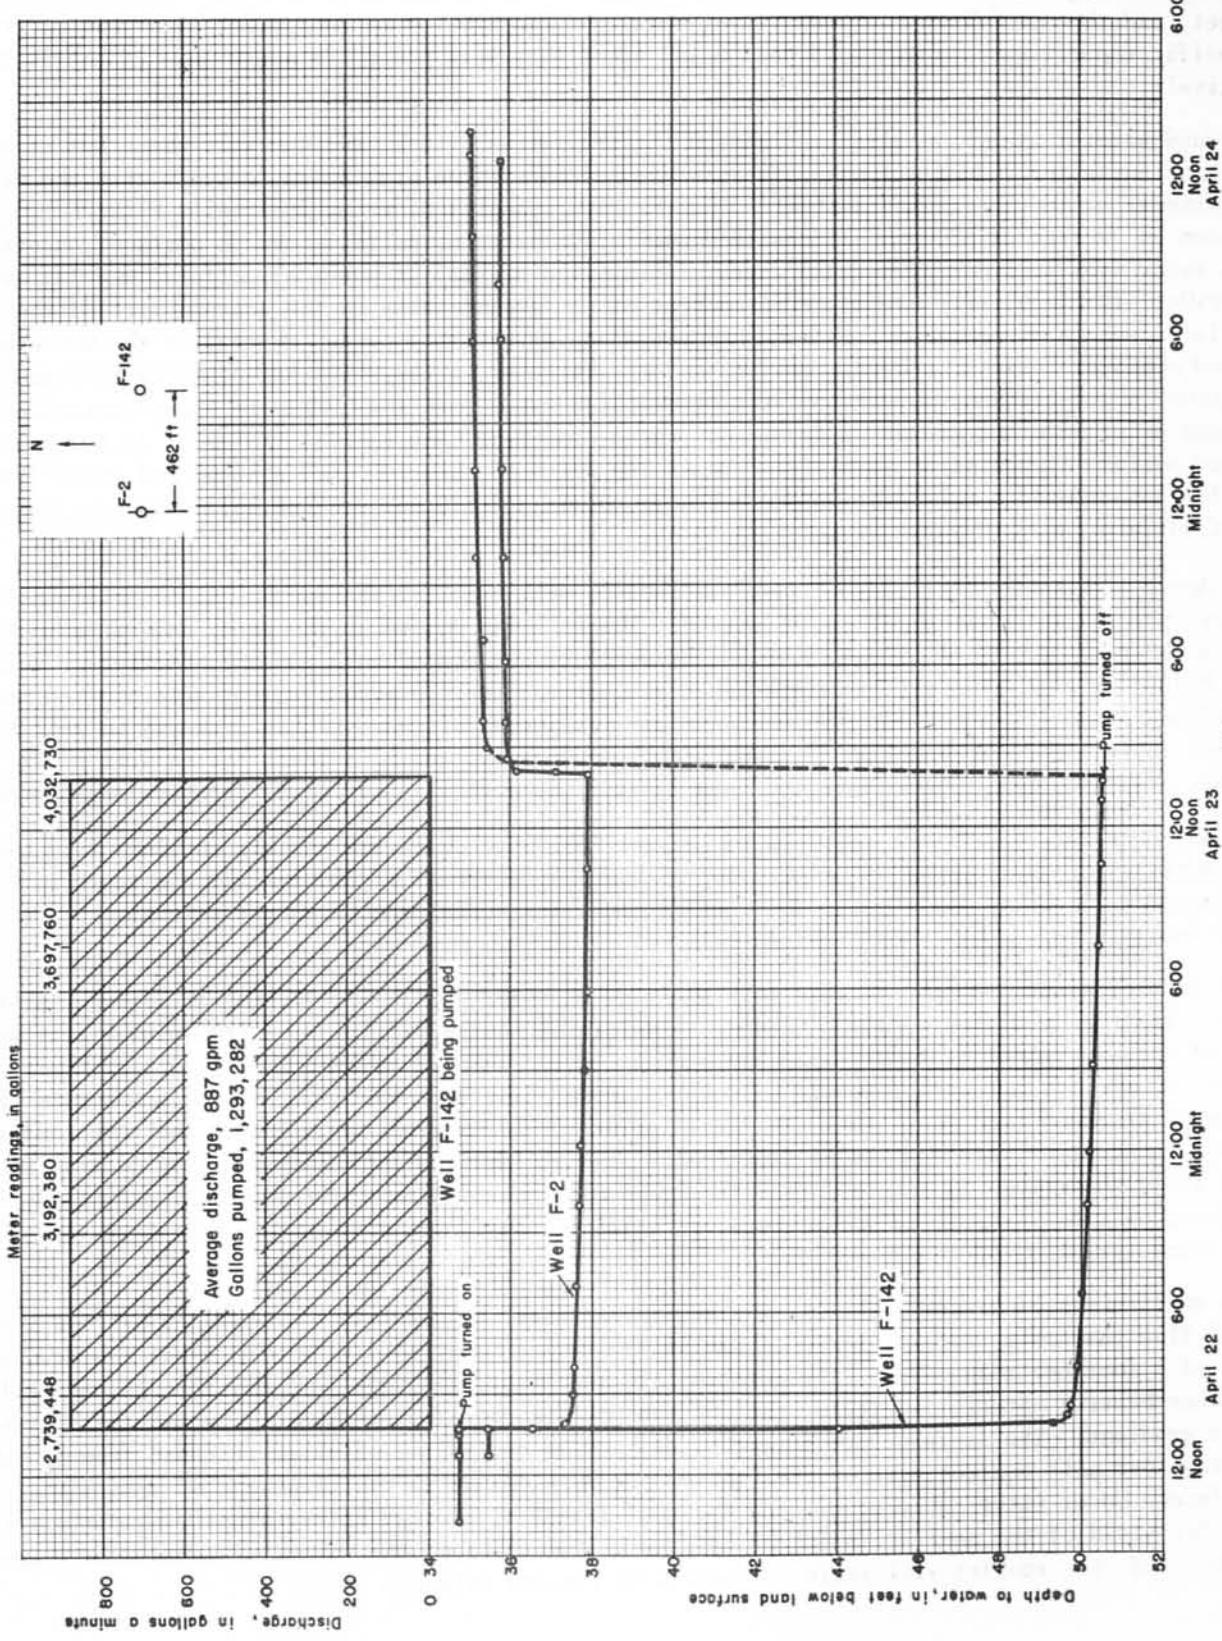

FIGURE 14.-Pumping test on well F-142

Texas Board of Water Engineers in cooperation with the U. S. Geological Survey

Bulletin 5704

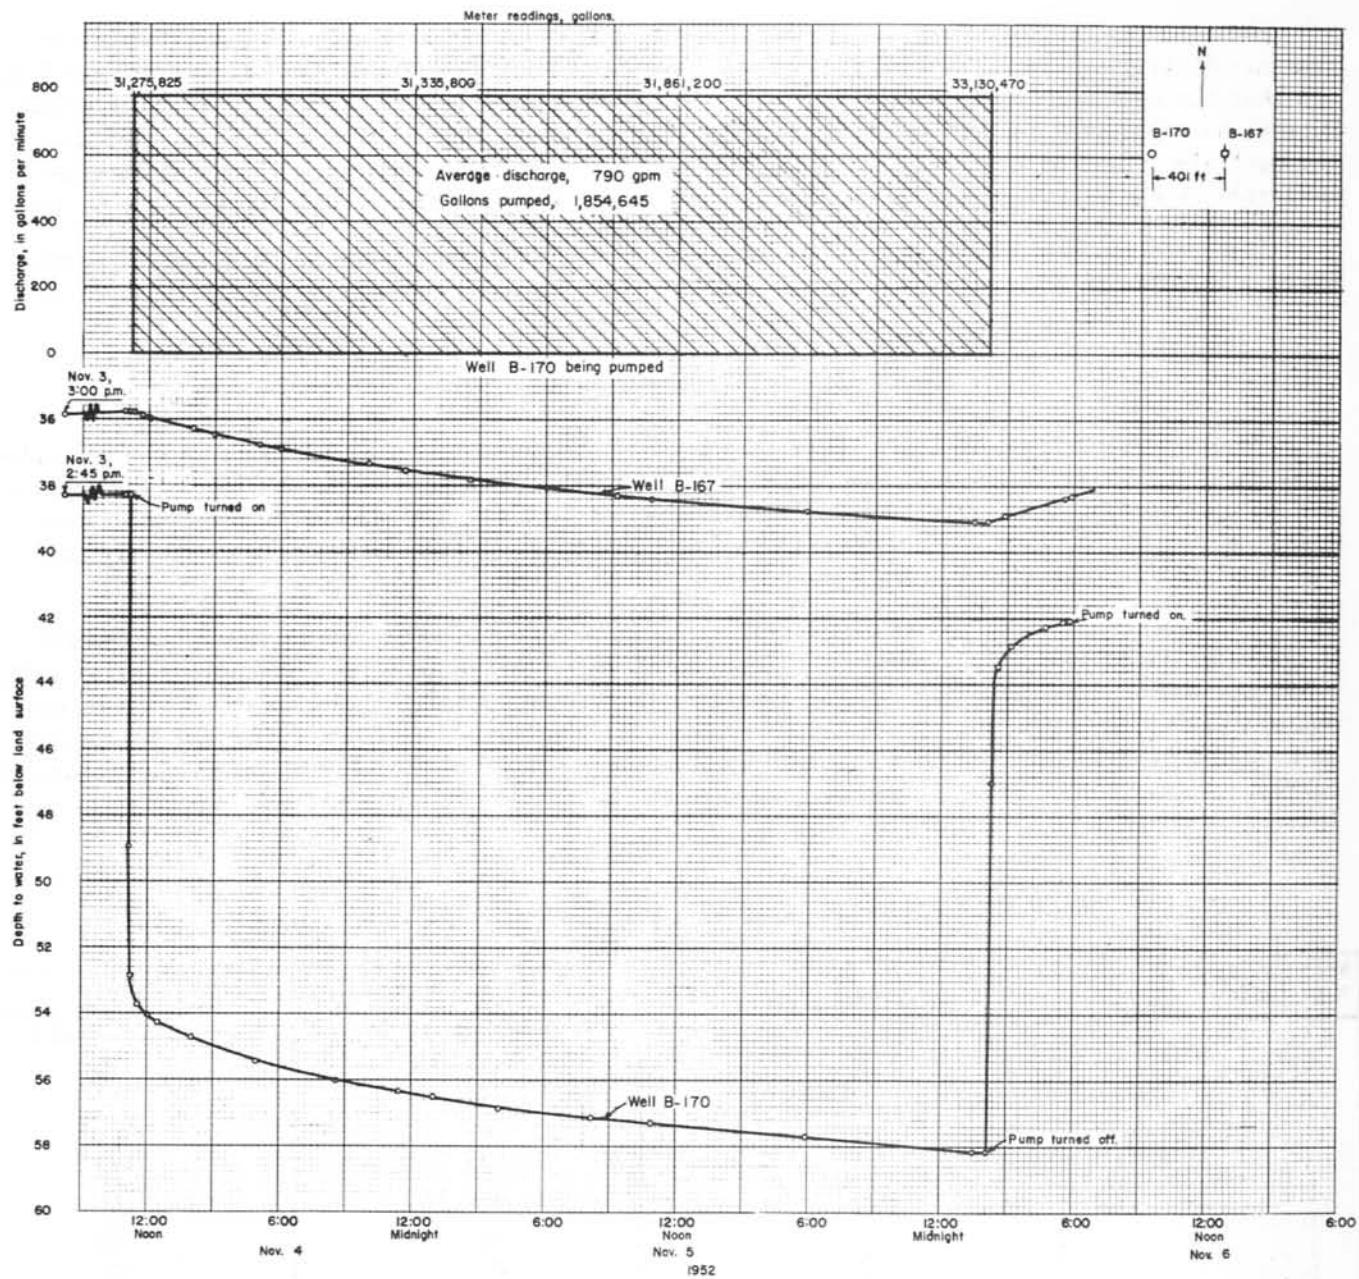

FIGURE 15.-Pumping test on well B-170.

The coefficients of transmissibility computed from the data obtained from the two tests in Lamb County were 63,000 gpm per foot in well B-167 and 153,000 gpm per foot in well F-2. The storage coefficients for the two tests were 0.018 at B-167 and 0.000013 at F-2. An analysis of the pumping-test data indicates that the aquifer varies considerably in short distances. The rapidity with which the effect of starting well F-142 was transmitted to well F-2 as compared to the longer time interval between the effect and the start of pumping well B-170 or well B-167 further supports the evidence of the lenticular character of the materials in the Ogallala formation.

Data obtained recently in pumping tests in the High Plains indicate that the coefficient of transmissibility generally is much less than that obtained during the tests at wells B-167 and F-2, and that the coefficient of storage is greater than that obtained during the tests at those wells. During the years 1938 to 1940, inclusive, a specific yield of about 15 percent was computed for the Ogallala formation by a comparison of the amount of water pumped with the volume of material unwatered in the Plainview and Hereford districts (Alexander, Broadhurst, and White, 1943, p. 15-17).

If a specific yield of 15 percent is assumed for the Ogallala formation, the total effective storage beneath the 150 square miles of sandhills may be computed to be about 2½ million acre-feet.

FLUCTUATION OF WATER LEVELS

Before pumping began in Lamb County, the ground-water reservoir was in approximate equilibrium; that is, the natural recharge was balanced by the natural discharge. Thus, artificial discharge in the form of pumping from irrigation wells removed water from storage and caused lowering of the water table. The decline of the water table from 1938 to 1952, therefore, has been roughly proportional to the quantity of water pumped.

Measurements of water levels in several wells in Lamb County were made by State and Federal agencies in 1914, 1934, 1936, and 1937. Since April 1937, the water levels in 45 observation wells have been measured at intervals ranging from a month to a year, and the records of these measurements are given in table 10. Since 1938, records of water-level measurements from selected wells in Lamb County have been included in water-supply papers published annually by the U. S. Geological Survey. A cross index of well numbers used in this report and corresponding well numbers used in the water-supply papers is given in table 6.

Table 6.- Observation-well numbers used in this report and corresponding numbers given in water-supply papers

Well no. in this report	Well no. in water-supply paper	Well no. in this report	Well no. in water-supply paper

C-74	57D		

Crops are irrigated in Lamb County during all four seasons, and in some years the pumps are operated nearly every month. Cotton, feed crops, and vegetables are irrigated during the period from May through September, and wheat during the winter and early spring. The amount of winter irrigation varies considerably, depending on the rainfall from year to year, and generally from December to March it is relatively small. A comparison of measurements made during the period from January to March in successive years, therefore, best shows the trend in water levels and the changes in storage of the ground-water reservoir.

During the period from January 1938 through March 1941 the water levels in 17 observation wells in Lamb County showed changes ranging from a decline of 2.7 feet to a rise of 0.4 foot. Of these wells, 11 in the area north of the sandhills showed an average decline of 1.2 feet. The greatest declines were in the older irrigated region in the western part of this area. Observation wells E-34 and F-13, remote from areas of ground-water withdrawals and in an area of recharge, showed an average rise in water level of 0.3 foot. The water levels in 4 wells south of the sandhills showed an average decline of 0.4 foot, and the declines increased toward the southeastern part of the county where pumping was large.

During the period 1941-43, inclusive, water levels in most observation wells showed a pronounced rise as a result of the exceptionally high rainfall and light pumping in 1941 and 1942. The rise in 17 observation wells ranged from 2.4 feet in well K-65 to 15.0 feet in well F-146, and averaged 6.5 feet. In general, the greatest rises were in the area north of the sandhills, where in 10 wells the average rise was 7.1 feet. These records indicate that recharge to the ground-water reservoir decreases eastward where the depth to water increases and the soils become tighter. Records of water levels in well E-1 in the sandhills show a rise of 4.6 feet from March 1941 to February 1943. The water level in well F-13 rose 6.0 feet from March 1941 to March 1942; records are not available to show whether it continued to rise during 1942. In the area south of the sandhills the water levels in five wells rose an average of 5.7 feet. The water level in well F-146, which is in an area favorable for recharge, rose 15 feet during the period March 1941 to February 1943, and continued to rise until February 1945.

Since 1943 the water levels in most wells have declined steadily, owing chiefly to an increase in pumping, but partly to the leveling off after the 1941-42 rains. The rate of decline is affected by the proximity of the well to areas of heavy ground-water withdrawal. During the period 1943-52 the decline in the water levels in 28 observation wells, most of which are in the irrigated parts of the county, ranged from 0.4 foot in well K-28 to 19.2 feet in well A-37 and averaged 12.0 feet, of which 8.8 feet or 70 percent occurred after 1946. The water levels in five wells in the irrigated area south of the sandhills declined an average of 9.7 feet.

During the period 1951-52 the decline of the water table in 18 wells in the northern part of the county ranged from 0.1 foot to 6.7 feet and averaged 3.0 feet. In grid A, the water levels in several wells declined less than 1 foot, and in well A-91 the water level rose 0.4 foot, indicating possible infiltration from a nearby stream bed. Water levels in wells E-34 and F-13 in the sandhills declined an average of 1.1 feet, whereas the level in well B-166 showed a net rise of 0.15 foot. Figure 16 shows the daily rainfall and daily fluctuation of the water level in well B-166 at plant "X" in the sandhills. Although the sandhills have a very high infiltration capacity, the water level in well B-166 showed no abrupt rise after the heavy rains of May 15-17. This lack of sharp response to rainfall was probably due to the low soil-moisture content of the dune materials which had to be replenished before water could percolate down to the water table. In the southern part of the county declines of water level ranged from less than 1 foot to 3.2 feet and averaged 1.5 feet. The greatest declines were in the southeastern part of the county.

Precipitation at Muleshoe during 1952 totaled 10.44 inches and was the lowest on record. Because of the subnormal precipitation and the increase in number of irrigation wells, the withdrawal of ground water and, consequently, the decline of the water table were greater in 1952 than in any previous year.

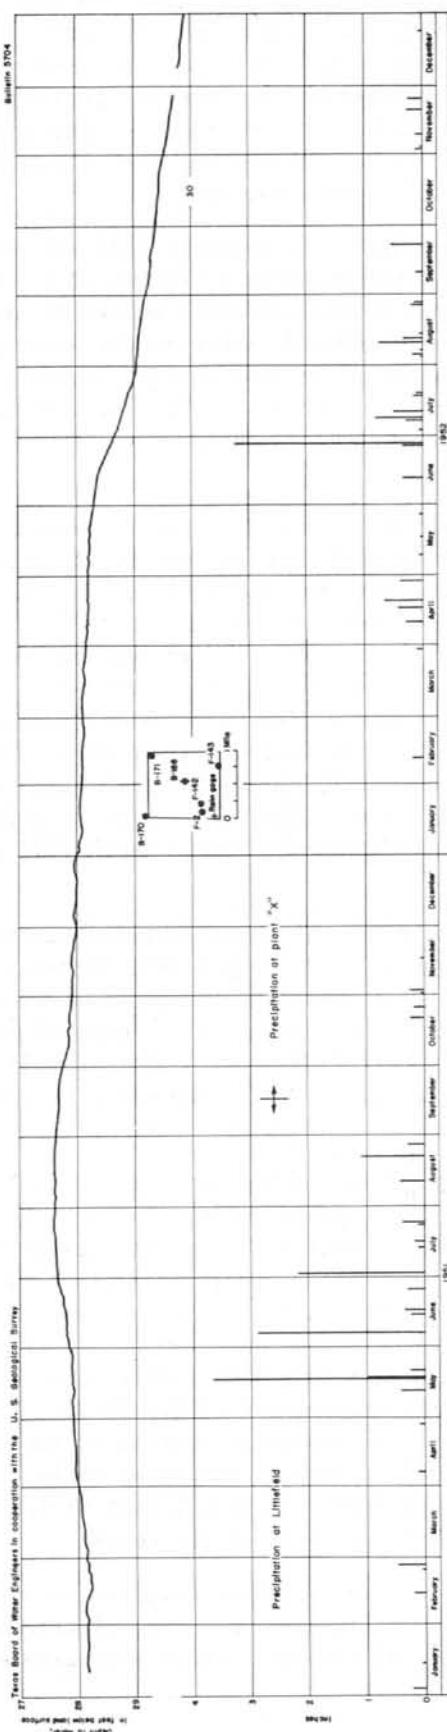

FIGURE 16. - Hydrograph of well B-166 and precipitation of Littlefield and plant "X".

The average net decline of water levels in 43 observation wells was 3.4 feet, or 1.1 feet greater than in 1951. The decline of the water table was fairly uniform throughout the irrigated sections of the county. The average net decline of the water table in 27 wells in the northern part of the county was 3.5 feet, and the average net decline in 14 wells south of the sandhills was 3.6 feet. Wells in the sandhills continued to show declines ranging from less than 1 foot in well E-34 to 1.4 feet in well F-13.

The water level in well B-166 was observed by means of an automatic water-stage recorder. A graph compiled from the recorder charts for 1951 and 1952 is shown in figure 16, together with the precipitation record at Littlefield and plant "X" for the same period. Figure 8 shows the fluctuations of the water levels in 10 other observation wells and the record of precipitation at Muleshoe.

The decline of the water level in observation well B-166, due to nearby pumping for industrial purposes, is shown in figure 16. The marked decline during June and July 1952 resulted from the withdrawal of approximately 40 million gallons of water from well F-142. About 120 million gallons of water was pumped from wells B-170 and B-171 during the period August to December 1952, inclusive, whereas less than 10 million gallons was pumped from well F-142. This shift in the center of pumping is reflected in the decreased rate of decline in well B-166 from August to December.

The fluctuation of water levels in most wells for which records are available varied widely during the period 1938-53, inclusive. Figure 17 shows, by means of lines connecting points of equal decline, that the greatest net declines are in those sections of the county that have been irrigated longest. In the sandhills and in other areas that are remote from pumping or are marginal to the irrigated regions, water levels declined little or were at a higher stage in January 1953 than in March 1938. Sufficient data are not available to delineate these areas.

QUALITY OF WATER

Ground water in Lamb County, in general, is usable for irrigation, public supply, industry, and stock. Analyses of water samples from 88 wells, 1 spring, and 2 lakes are given in table 11. Standards that have been established for judging the suitability of water for irrigation are based on the total concentration of dissolved solids, the percentage of sodium, and the quantity of boron in the water. According to a classification by Wilcox (1948) based on specific conductance (which is directly related to dissolved solids content) and percent sodium, most of the water ranges from "good" to "permissible" for irrigation (fig. 18).

Boron is an element required in very small amounts for plant growth, but it is exceedingly toxic at concentrations only slightly above optimum. It is not usually present in large amounts. Boron toxicity may be indicated by yellowing and mottling of leaves, and in severe cases by defoliation of plants. Permissible limits of boron in several classes of irrigation water are shown in table 7. In 13 samples of water used for irrigation in Lamb County, the boron content ranged from 0.02 to 0.89 ppm. Boron, therefore, is believed to be no problem in Lamb County.

Table 7.- Permissible limits for boron in several classes of irrigation water. (Scofield, 1936, p.286)

Rating	Classes of water	Sensitive crops (ppm)	Semitoriental crops (ppm)	Tolerant crops (ppm)
1	Excellent	< 0.33	< 0.67	< 1.00
2	Good	0.33 to 0.67	0.67 to 1.33	1.00 to 2.00
3	Permissible	0.67 to 1.00	1.33 to 2.00	2.00 to 3.00
4	Doubtful	1.00 to 1.25	2.00 to 2.50	3.00 to 3.75
5	Unsuitable	> 1.25	> 2.50	> 3.75

Bulletin 5704

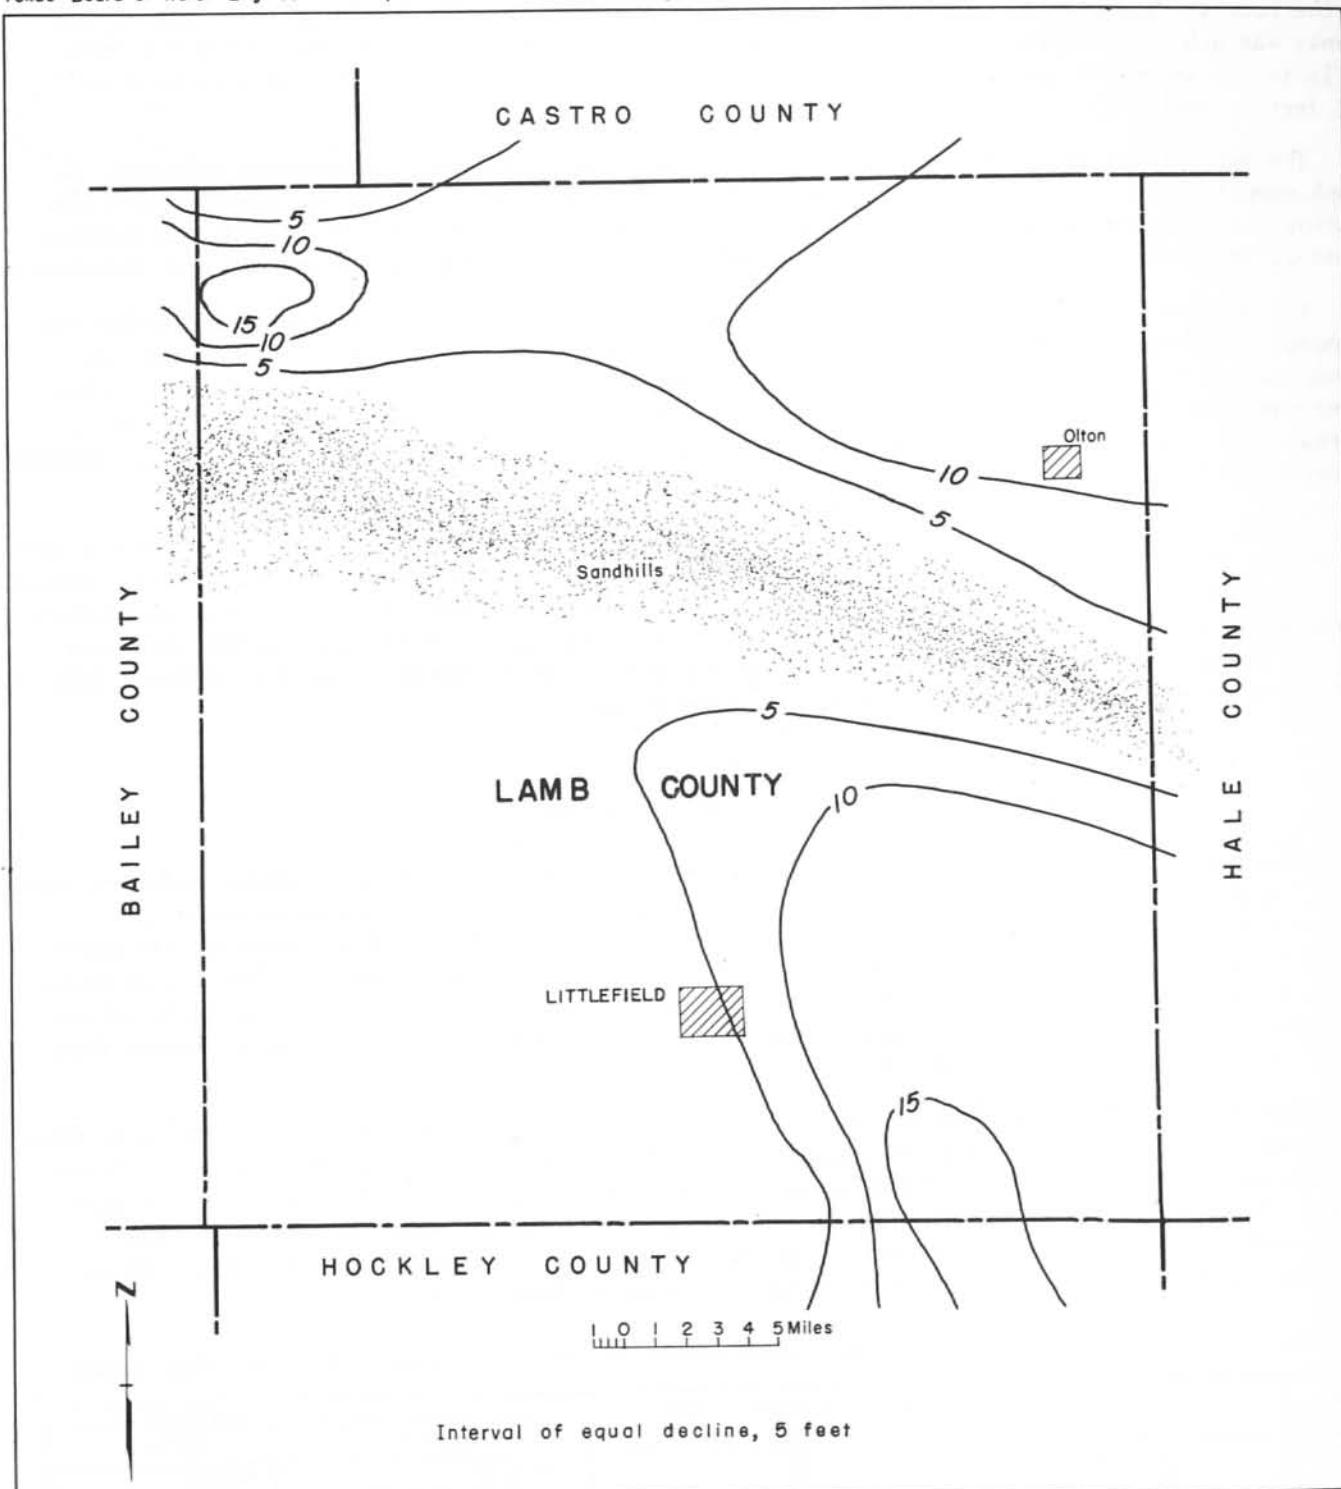

FIGURE 17. - Decline of water levels in Lamb County, 1938-53.

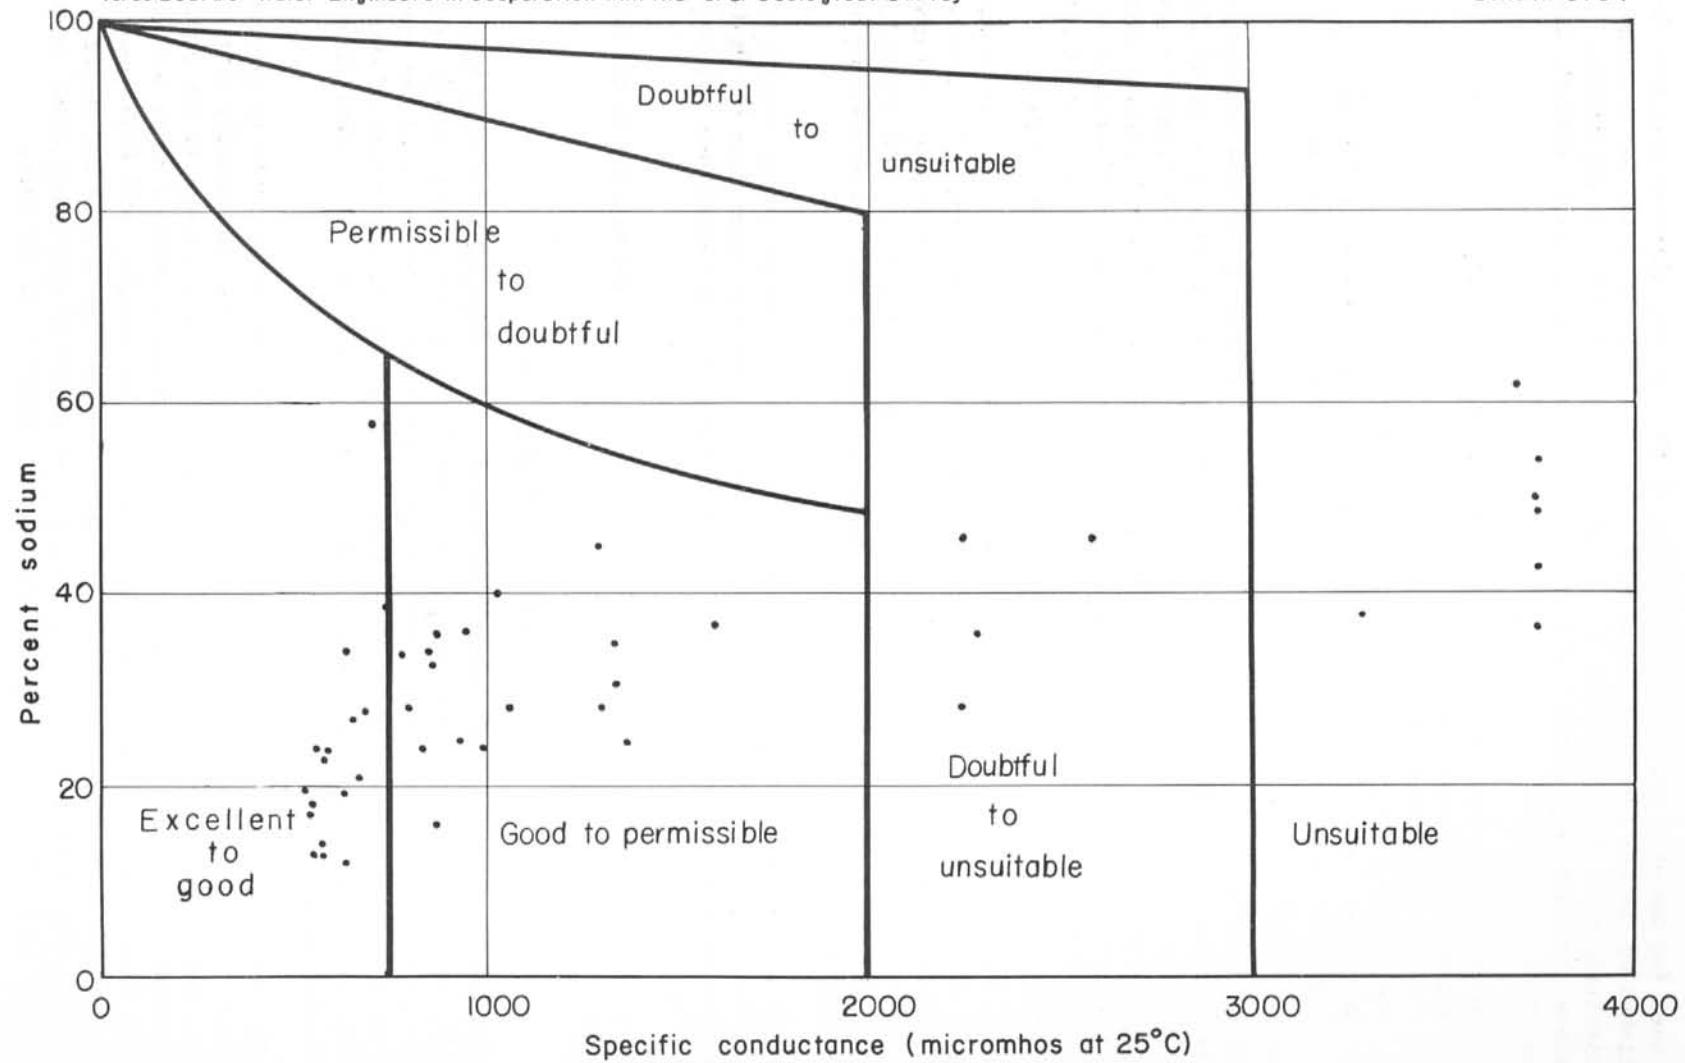

FIGURE 18.- Classification of ground water for irrigation in Lamb County (Wilcox, 1948, p. 26).

Water used for domestic and municipal supplies should conform, whenever possible, to the standards established by the United States Public Health Service (1946, p. 384), for drinking and culinary water on interstate carriers, which have been adopted by many state health departments. These standards place the following concentration limits on the important minerals commonly found in solution in ground water:

Iron (Fe) and manganese (Mn) together should not exceed 0.3 ppm.
 Magnesium (Mg) should not exceed 125 ppm.
 Chloride (Cl) should not exceed 250 ppm.
 Sulfate (SO_4) should not exceed 250 ppm.
 Dissolved solids should not exceed 500 ppm in water of good chemical quality.
 However, if such water is not available, a dissolved-solids content of 1,000 ppm may be permitted.

The effect of fluoride in drinking water on the teeth of growing children was discussed by Dean (1936, 1938). Evidence indicates that drinking water containing more than 1.5 ppm of fluoride produces significant mottling of teeth, whereas smaller amounts of fluoride lessen the incidence of tooth decay. The Texas State Department of Health now recommends a fluoride concentration of 1.0 to 1.5 ppm. Analyses of 55 water samples in Lamb County showed an average fluoride content of 2.7 ppm and a range from 0.5 to 8.8 ppm. Of the 55 samples, only 4 showed a fluoride content within the recommended range of 1.0 to 1.5 ppm, and only 1 showed a content less than 1.0 ppm.

The water from the Ogallala formation in Lamb County generally is a hard calcium magnesium bicarbonate water. Of 70 samples (table 11), 60 samples had concentrations (ppm) of magnesium greater than calcium, therefore the water generally cannot be classed as calcium bicarbonate. Bicarbonate is the predominant anion. The dissolved-solids content ranges from about 230 to 1,600 ppm and averages 685 ppm, except in the vicinity of the alkali lakes and seeps, where higher concentrations of dissolved solids have been observed.

Although few wells in Lamb County obtain water from the Cretaceous rocks, records of those few indicate that the water is generally higher in dissolved solids than water from the Ogallala. Water from the Cretaceous rocks, like that in many places from the Ogallala formation, may contain magnesium in excess of calcium.

The quality of water in various parts of Lamb County is discussed briefly in the section "Development of Ground Water."

WELL CONSTRUCTION

In recent years, most of the municipal, industrial, and irrigation wells have been drilled by the rotary method, which in large part has replaced the percussion or cable-tool method. In general, the well diameter is about 18 inches, but in many of the older wells the diameter of the casing has been reduced two or more times. The reduced diameter of the casing in the lower part of these wells has precluded lowering of the large-diameter pumps and has resulted in the abandonment of many wells as the water levels decline.

The wells are generally finished with casing slotted from the water table to the bottom. The general practice in Lamb County has been to burn slots in the casing, and usually little effort is made to relate the width of the slot to the diameter of the sand particles. If the slots are too large, considerable quantities of sand enter the well, resulting in wear of pumps and casing and eventually the loss of the well by collapse of the walls. For example, well F-99 pumped so much fine sand as to cause a collapse of the well, resulting in the loss of pump and casing. On the other hand, slots that are too small, or an insufficient number of slots, may cause excessive "entrance losses" in head, thereby reducing the specific capacity of the wells.

Most of the pumps in use are high-speed turbines powered by internal-combustion engines fueled by butane, although a small, but increasing, number of pumps are powered by electric motors (fig. 19). In recent years the pump settings of an ever-increasing number of wells have had to be lowered considerably, owing to the decline of the water table. Numerous wells have been reported by the owners to have decreased in discharge at the peak of the irrigation season, thus necessitating a lowering of the pump setting. Most of the changes have been in the older, more heavily pumped districts. For example, the pump setting in well M-57 was lowered from 120 to 160 feet during the period 1945-50, and that in well M-97 was lowered from 170 to 204 feet during the period 1941-50.

FIGURE 19.- Irrigation well C-235, Lamb County, Tex.

FUTURE DEVELOPMENT

Additional large supplies of ground water suitable for irrigation, industrial, and municipal needs are available from the Ogallala formation in Lamb County. The largest undeveloped source is the 150 square miles of sandhills, where an estimated 2½ million acre-feet of ground water is in storage. Much of this land is rolling and sandy and generally unsuitable for farming. Nevertheless, a considerable acreage is relatively flat and has a clayey soil that could be farmed and irrigated.

When closely spaced wells are pumped, the cones of depression surrounding them overlap, and the excessive interference results in a decrease in the discharge or necessitates a lowering of the pumping level, or both. However, further expansion of irrigation in the northern part of the county is possible if wells are properly spaced. In the irrigated part of the area south of the sandhills there are presently about four wells per square mile and the discharge from many of the wells is reported to decrease during the irrigating season. Therefore, further expansion of irrigation may result in local overconcentration of wells and continued or accelerated decrease in well discharge. It is not likely that large-scale irrigation can be developed in the southwestern part of the county because of the thinness of the saturated materials and the presence of highly mineralized water in the vicinity of the alkali lakes. However, in those parts of that area where mineralization is not a factor, the supply of water in the Ogallala is adequate for domestic and livestock requirements.

Ground-water supplies from the basal sand and gravel of the Kiamichi formation are believed to be too highly mineralized and too small for use other than watering stock.

Electric logs indicate that the water in the Triassic rocks is too highly mineralized for most purposes. Although mineralization appears to decrease westward, the quantity of water available to wells is likely to be too small for irrigation.

Well B-26				
Owner: W. H. Williams. Driller: Green Machinery Co.				
Quaternary and Tertiary, undifferentiated:				
Soil	4	4	Rock	7 122
Caliche, rocky	58	62	Clay and rock	33 155
Sand, coarse, red	43	105	Sand, fine, and rock	40 195
Sand, coarse, and rock	10	115	Sand, coarse, and gravel	21 216

Table 9.- Drillers' logs of wells in Lamb County--Continued

	Thickness (feet)	Depth (feet)		Thickness (feet)	Depth (feet)
Well B-43					
Owner:	A. C. Gettys.	Driller:	M. A. Patton		
Quaternary and Tertiary, undifferentiated:					
Soil	4	4	Sand and clay	17	128
Clay	6	10	Rock	6	134
Sand, red	8	18	Gravel, sandy	6	140
Clay	24	42	Clay	12	152
Sand, red	6	48	Sand	48	200
Clay	27	75	Clay	8	208
Sand, water	11	86	Sand	13	221
Sandrock	3	89	Gravel	15	236
Sand	22	111			
Well B-47					
Owner:	W. H. Jones.	Driller:	Green Machinery Co.		
Quaternary and Tertiary, undifferentiated:					
Soil	5	5	Clay, hard	15	110
Clay	15	20	Clay, hard, and rock	15	125
Clay and rocks	30	50	Sand, good	30	155
Clay, soft	15	65	Sand	60	215
Sand, good	15	80	Sand and gravel	10	225
Clay and rocks	15	95	Triassic: Clay	5	230
Well B-52					
Owner:	Mrs. Ruby Hodge.	Driller:	Green Machinery Co.		
Quaternary and Tertiary, undifferentiated:					
Soil	5	5	Sand	16	115
Clay and caliche	63	68	Rock	2	117
Sand	28	96	Clay and shale	25	142
Rock	3	99	Sand and gravel	78	220
Well B-56					
Owner:	J. Boseman.	Driller:	Bradford Supply Co.	Reported altitude 3757.34 feet.	
Quaternary and Tertiary, undifferentiated:					
Soil	6	6	Sand, clayey	3	69
Caliche	10	16	Clay	12	81
Sandstone	6	22	Sand	31	112
Sand, medium	8	30	Rock	3	115
Caliche	12	42	Sand	97	212
Clay	12	54	Sand and gravel	18	230
Rock, clayey	12	66	Gravel, good water	14	244

Thickness (feet)	Depth (feet)		Thickness (feet)	Depth (feet)
Well B-57				
Owner: H. F. Hodge. Driller: Green Machinery Co. Reported altitude 3750.06 feet.				
Quaternary and Tertiary, undifferentiated:				
Soil	4	4	Sand	8 153
Shale	31	35	Sandrock	10 163
Clay and shale	40	75	Clay	15 178
Rock, soft	4	79	Sand and gravel	55 233
Sand	33	112	Rock	1 234
Rock, hard	33	145		
Well B-87				
Owner: John Laing. Driller: Leo Koger.				
Quaternary and Tertiary, undifferentiated:				
Soil	2	2	Caliche and sand	11 62
Rock	1	3	Clay, red	6 68
Sand and red clay	17	20	Sand, red, water	13 81
Caliche	17	37	Clay, red	11 92
Sand, red, water	14	51	Packsand	12 104
Well B-98				
Owner: W. O. Wood. Driller: Bud Gibbon.				
Quaternary and Tertiary, undifferentiated:				
Soil	6	6	Clay	7 109
Caliche	39	45	Sand	13 122
Clay	10	55	Rock	4 126
Caliche	10	65	Sand	14 140
Caliche, rock	10	75	Clay	15 155
Sand	27	102	Sand and gravel	13 168
Well B-102				
Owner: J. W. Kelly. Driller: Green Machinery Co.				
Quaternary and Tertiary, undifferentiated:				
Soil	5	5	Rock	2 120
Caliche	15	20	Sand	28 148
Clay and caliche	30	50	Clay	7 155
Clay	8	58	Sand	15 170
Sand	7	65	Sand and shale	15 185
Sand and shale	15	80	Sand and gravel	30 215
Sand	38	118

	Thickness (feet)	Depth (feet)		Thickness (feet)	Depth (feet)
Well B-103					
Owner:	Carl Seymour.	Driller:	S. J. Tarkenton.		
Quaternary and Tertiary, undifferentiated:					
Soil	3	3	Rock, flint	5	80
Caliche	47	50	Clay, red	10	90
Sand, dry	10	60	Sand, water	30	120
Clay, red	10	70	Clay, red	10	130
Sand, water	5	75	Sand, water	20	150
Well B-118					
Owner:	A. E. Wheatley.	Driller:	Green Machinery Co.		
Quaternary and Tertiary, undifferentiated:					
Soil	5	5	Clay and rock	5	70
Caliche	15	20	Sand	25	95
Clay	15	35	Clay, joint, and rock	15	110
Clay, soft	15	50	Sand, red, fine	60	170
Rock and clay	15	65	Sand, coarse, and gravel	30	200
Well B-122					
Owner:	Roy Woods.	Driller:	Green Machinery Co.		
Quaternary and Tertiary, undifferentiated:					
Soil	6	6	Sand and shale	19	95
Caliche	8	14	Rock	8	103
Clay	10	24	Packsand, hard	25	128
Sand, dry	8	32	Sand and shale	18	146
Shale	26	58	Sand	38	184
Sand	18	76	Sand and gravel	36	220
Well B-138					
Owner:	A. W. Gover.	Driller:	Bud Gibbons.		
Quaternary and Tertiary, undifferentiated:					
Soil	5	5	Rock	4	54
Caliche and sand	21	26	Sand	16	70
Rock	2	28	Sand, tight	30	100
Sand, dry	14	42	Rock	5	105
Rock	2	44	Sand	47	152
Sand	6	50

	Thickness (feet)	Depth (feet)		Thickness (feet)	Depth (feet)
Well B-158					
Owner:	Virgil Lewis.	Driller:	Consolidated Oil & Gas Co.		
Quaternary and Tertiary, undifferentiated:					
Soil	12	12	Clay	17	125
Caliche	33	45	Sand	15	140
Rock	7	52	Sand and shale	25	165
Sand	18	70	Sand	8	173
Shale	38	108			
Well B-165					
Owner:	Southwestern Public Service Co.	Driller:	D. L. McDonald.	Reported altitude 3685.95 feet.	
Quaternary and Tertiary, undifferentiated:					
Sand, clayey, red	20	20	Sand, red	8	130
Caliche	23	43	Sand, clayey and gravel	16	146
Sand, clayey, red	27	70	Clay, sandy	4	150
Sand, clayey, gray	40	110	Sand and gravel, clean, and clay hills	40	190
Sand, red	6	116	Triassic: Clay, red	10	200
Clay, red	6	122			
Well B-166					
Owner:	Southwestern Public Service Co.	Driller:	D. L. McDonald.	Reported altitude 3662.87 feet.	
Quaternary and Tertiary, undifferentiated:					
Sand	4	4	Sand and gravel	12	128
Caliche, and clay, hard	16	20	Sand and gravel and sandstone stringers	12	140
Caliche	12	32	Sand and gravel	10	150
Caliche and sand	13	45	Sand and gravel and clay streaks	35	185
Clay, sandy	5	50	Sand and gravel and clay	6	191
Sand and clay	20	70	Triassic: Red beds	11	202
Sand and clay, and sandstone stringers	25	95			
Sand and clay	13	108			
Sand and a little gravel	8	116			
Well B-167					
Owner:	Southwestern Public Service Co.	Driller:	D. L. McDonald.	Reported altitude 3674.1 feet.	
Quaternary and Tertiary, undifferentiated:					
Sand, clayey	15	15	Sand and gravel	21	152
Caliche	35	50	Sand, fine, and gravel, loose formation; caves	15	167
Sand, red, muddy	10	60	Clay, brown	1	168
Sand, red, clean	20	80	Sand, fine, gray	7	175
Sand, red, soft, and pebbles; loose formation, water-bearing	11	91	Sand, coarse, and gravel, water	25	200
Sandstone, hard	1	92	Triassic: Red beds	7	207
Sand, red, and pebbles, water-bearing	20	112			
Clay, sandy, white	13	125			
Rock, white, sand and gravel	6	131			

Table 9.- Drillers' logs of Lamb County--Continued

	Thickness (feet)	Depth (feet)		Thickness (feet)	Depth (feet)
Well B-168					
Owner:	Southwestern Public Service Co.	Driller:	D. L. McDonald.	Reported altitude	3676.3 feet.
Quaternary and Tertiary, undifferentiated:					
Sand, clayey	3	3	Clay, red	3	138
Clay, sandy	22	25	Sand, soft, and clay balls ...	6	144
Caliche	20	45	Sand and gravel	11	155
Sand, clayey, red	15	60	Clay, red	1	156
Sand, clayey, gray	20	80	Sand and gravel	33	189
Sand, red, and sand pebbles	5	85	Triassic: Red beds	1	190
Sand, clayey, red	10	95			
Clay, sandy, white	10	105			
Sand, clayey, sand pebbles and white sandstone	30	135			
Well B-169					
Owner:	Southwestern Public Service Co.	Driller:	D. L. McDonald.	Reported altitude	3687.5 feet.
Quaternary and Tertiary, undifferentiated:					
Sand	4	4	Sand and clay	10	120
Caliche and clay	53	57	Sand and clay, and caliche ..	10	130
Sand and caliche	10	67	Sand and gravel	60	190
Sand, fine, red	13	80	Triassic: Red beds	3	193
Sand and clay stringers	30	110			
Well B-170					
Owner:	Southwestern Public Service Co.	Driller:	D. L. McDonald.	Reported altitude	3676.65 feet.
Quaternary and Tertiary, undifferentiated:					
Soil, sandy	3	3	Sand, white	13	128
Clay and sand	17	20	Sand, and clay stringers	12	140
Caliche	15	35	Sandstone, soft	10	150
Caliche and sand	20	55	Sand, soft	10	160
Sand	10	65	Sand and gravel	25	185
Sand, fine, red	10	75	Sand	16	201
Sand	30	105	Triassic: Clay, red	2	203
Sand and sandstone stringers	10	115			
Well B-171					
Owner:	Southwestern Public Service Co.	Driller:	D. L. McDonald.		
Quaternary and Tertiary, undifferentiated:					
Soil, sandy	5	5	Sand and sandstone stringers	10	120
Clay and caliche	27	32	Sand	10	130
Sand	48	80	Sand and gravel	20	150
Sandstone, hard	5	85	Sand	40	190
Sand	6	91	Sand and gravel and boulders	4	194
Sand and sandstone stringers	9	100	Triassic: Clay, red	2	196
Sand, soft	10	110

a/ Sulfate less than 10 ppm.

b/ Includes equivalent of 10 ppm carbonate (CO_3^{2-}).c/ Includes equivalent of 52 ppm carbonate (CO_3^{2-}).d/ Includes equivalent of 7 ppm carbonate (CO_3^{2-}).e/ Includes equivalent of 22 ppm carbonate (CO_3^{2-}).f/ Includes equivalent of 9 ppm carbonate (CO_3^{2-}).g/ Includes equivalent of 18 ppm carbonate (CO_3^{2-}).
